FOR IMMEDIATE RELEASE

New Editor, New Vision for *ACS Surgery*

BC Decker Inc, publisher of the acclaimed general surgical reference, *ACS Surgery*, is honored to announce the appointment of Stanley W. Ashley, MD, FACS as the new Editor-in-Chief.

Dr. Ashley is the Frank Sawyer Professor and Vice Chairman of the Department of Surgery, and Program Director of the General Surgery Residency Program at Brigham and Women's Hospital/Harvard Medical School, Boston. He is also Chief of General Surgery for Harvard Vanguard Medical Associates.

As the new Editor-in-Chief, Dr. Ashley brings his estimable experience in, and unique vision of, surgery to bear on *ACS Surgery*, an official publication of the American College of Surgeons. "The opportunity to adapt *ACS Surgery* to the evolving needs of surgical residents and practicing surgeons is extremely exciting to me," remarked Dr. Ashley.

"Stan Ashley will be a wonderful new editor of *ACS Surgery*, who will build on the outstanding work Dr. Souba did in transitioning the original loose-leaf work into the modern era. Dr. Ashley will continue that trend by taking this excellent educational product to the next level," said ACS Executive Director Thomas R. Russell, MD, FACS.

In addition to many exciting changes, Dr. Ashley envisions adding operative videos to the online home of *ACS Surgery*, www.acssurgery.com. He believes that these videos, teaching slide sets, and pod casts will enhance the educational experience for residents and practicing surgeons before entering the OR. He also would like the text to begin to integrate with the new general surgery residency curriculum being developed by the Surgical Committee on Resident Education (SCORE). He also hopes to expand the scope of the work by including chapters by a variety of experts with differing perspectives on general surgery and the subspecialties. Together with Decker, Dr Ashley will promulgate the effort to make *ACS Surgery* an internationally adopted surgical reference.

Optimism for the new Editor-in-Chief is described succinctly by Brian Decker, President and Publisher: "We are persuaded that Dr. Ashley's stewardship will enhance the already remarkable success of *ACS Surgery*. The work draws its strength from its rich history, but its vitality stems from the fresh vision that Dr. Ashley brings to the enterprise. Since its first incarnation as *Scientific American Surgery*, this work has been the benchmark for innovation in surgical education. We expect the track record to be extended during the Ashley regime."

About Stanley W. Ashley, MD, FACS

Stanley W. Ashley is a graduate of Oberlin College and Cornell University Medical College. He completed a residency in general surgery at Washington University in St. Louis and subsequently joined the faculty. He spent seven years at UCLA before assuming his current position at Brigham and Women's Hospital/ Harvard Medical School in 1997. Dr. Ashley is a gastrointestinal surgeon whose primary interests are diseases of the pancreas and inflammatory bowel disease. His research, which has been funded by the VA the NIH, has examined the pathophysiology of small bowel and pancreas. An author of more than 200 journal articles, he serves on numerous editorial boards, including the Journal of Gastrointestinal Surgery, the Journal of the American College of Surgeons, and Current Problems in Surgery. He is a director of the American Board of Surgery and member of the Board of Trustees of the Society for Surgery of the Alimentary Tract.

About BC Decker Inc

BC Decker Inc has published some of the most important works in medicine and surgery, including Cameron's *Current Surgical Therapy*, Cameron-Sandone's *Atlas of Gastrointestinal Surgery*, and Grillo's *Surgery of the Trachea*. Decker is respected for the quality of its titles and renowned for its authors. The company realizes half of its sales outside the United States through its relationships with the best international houses. Decker also publishes *ACP Medicine*, née *Scientific American Medicine*, and 20 specialty journals in medicine and dentistry. Every Decker publication is available in print and digital formats. The company's publishing partners include American College of Surgeons, American Board of Surgery, American Board of Otolaryngology, American Academy of Otolaryngology, and the American College of Physicians.

About the American College of Surgeons

The American College of Surgeons is a scientific and educational organization of surgeons that was founded in 1913 to raise the standards of surgical practice and to improve the care of the surgical patient. The College is dedicated to the ethical and competent practice of surgery. Its achievements have significantly influenced the course of scientific surgery in America and have established it as an important advocate for all surgical patients. The College has more than 76,000 members and is the largest organization of surgeons in the world.

1 PROFESSIONALISM IN SURGERY

Jo Shapiro, MD, FACS, Steven M. Steinberg, MD, FACS, and Wiley W. Souba, MD, ScD, MBA, FACS

Over the past decade, the American health care system has had to cope with and manage an unprecedented amount of change. As a consequence, the medical profession has been challenged along the entire range of its cultural values and its traditional roles and responsibilities. It would be difficult, if not impossible, to find another social issue directly affecting all Americans that has undergone as rapid and remarkable a transformation—and oddly, a transformation in which the most important protagonists (i.e., the patients and the doctors) remain dissatisfied.¹

Nowhere is this metamorphosis more evident than in the field of surgery. Marked reductions in reimbursement, explosions in surgical device biotechnology, a national medical malpractice crisis, and the disturbing emphasis on commercialized medicine have forever changed the surgical landscape, or so it seems. The very foundation of patient care—the doctor-patient relationship—is in jeopardy. Surgeons find it increasingly difficult to meet their responsibilities to patients and to society as a whole. In these circumstances, it is critical for us to reaffirm our commitment to the fundamental and universal principles and values of medical professionalism.

The concept of medicine as a profession grounded in compassion and sympathy for the sick has come under serious challenge.² One eroding force has been the growth and sovereignty of biomedical research. Given the high position of science and technology in our societal hierarchy, we may be headed for a form of medicine that includes little caring but becomes exclusively focused on the mechanics of treatment, so that we deal with sick patients much as we would a flat tire or a leaky faucet. In such a form of medicine, healing becomes little more than a technical exercise, and any talk of morality that is unsubstantiated by hard facts is considered mere opinion and therefore carries little weight.

The rise of entrepreneurialism and the growing corporatization of medicine also challenge the traditions of virtue-based medical care. When these processes are allowed to dominate medicine, health care becomes a commodity. As Pellegrino and Thomasma remark, “When economics and entrepreneurship drive the professions, they admit only self-interest and the working of the marketplace as the motives for professional activity. In a free-market economy, effacement of self-interest, or any conduct shaped primarily by the idea of altruism or virtue, is simply inconsistent with survival.”²

Another profound change in the practice of medicine is the shift from a largely autonomous focus, with the surgeon both shouldering tremendous personal responsibility and wielding considerable control and independence, to a complex, team-based focus. Within this new paradigm, leadership of a surgical team requires vastly different competencies than

were previously required or even valued. Many surgeons have flourished in this new environment: leading a cohesive team dedicated to excellent outcomes is highly rewarding. Unfortunately, however, as a profession, we have not explicitly taught these teamwork and leadership skills, nor have we always helped our colleagues remediate deficiencies in such skills.

The Meaning of Professionalism

Professionalism is the basis of our contract with society. A profession is a collegial discipline that regulates itself by means of mandatory, systematic training. It has a base in a body of technical and specialized knowledge that it both teaches and advances; it sets and enforces its own standards; and it has a service orientation, rather than a profit orientation, enshrined in a code of ethics.³⁻⁵ To put it more succinctly, a profession has cognitive, collegial, and moral attributes. These qualities are well expressed in the familiar sentence from the Hippocratic oath: “I will practice my art with purity and holiness and for the benefit of the sick.”

Historically, the legitimacy of medical authority is based on three distinct claims^{2,6}: first, that the knowledge and competence of the professional have been validated by a community of peers; second, that this knowledge has a scientific basis; and third, that the professional’s judgment and advice are oriented toward a set of values. These aspects of legitimacy correspond to the collegial, cognitive, and moral attributes that define a profession.

The American College of Surgeons (ACS) Task Force on Professionalism has developed a Code of Professional Conduct,⁷ which emphasizes the following four aspects of professionalism:

1. A competent surgeon is more than a competent technician.
2. Whereas ethical practice and professionalism are closely related, professionalism also incorporates surgeons’ relationships with patients and society.
3. Unprofessional behavior must have consequences.
4. Professional organizations are responsible for fostering professionalism in their membership.

Specifically, the ACS Code of Professional Conduct includes tenets of professionalism that relate to both our care of individual patients and our role in society [see Table 1].

The Accreditation Council on Graduate Medical Education (ACGME) has identified six competencies that must be demonstrated by the surgeon: (1) patient care; (2) medical knowledge; (3) practice-based learning and improvement; (4) interpersonal and communication skills; (5) professionalism; and (6) systems-based practice. These competencies are now being integrated into the training programs of all accredited surgical residencies.

Being a professional demands unwavering personal integrity and a commitment to lifelong learning and improvement. It

Financial disclosure information is located at the end of this chapter before the references.

Table 1 American College of Surgeons' Code of Professional Conduct²⁷

During the continuum of pre-, intra-, and postoperative care, we accept responsibilities to

- Serve as effective advocates for our patients' needs;
- Disclose therapeutic options, including their risks and benefits;
- Disclose and resolve any conflict of interest that might influence the decisions of care;
- Be sensitive and respectful of patients, understanding their vulnerability during the perioperative period;
- Fully disclose adverse events and medical errors;
- Acknowledge patients' psychological, social, cultural, and spiritual needs;
- Encompass within our surgical care the special needs of terminally ill patients;
- Acknowledge and support the needs of patients' families; and
- Respect the knowledge, dignity, and perspective of other healthcare professionals.

Our profession is also accountable to our communities and to society. In return for their trust, as Fellows of the American College of Surgeons, we accept responsibilities to

- Provide the highest quality of surgical care;
- Abide by the values of honesty, confidentiality, and altruism;
- Participate in lifelong learning;
- Maintain competence throughout our surgical careers;
- Participate in self-regulation by setting, maintaining, and enforcing practice standards;
- Improve care by evaluating its processes and outcomes;
- Inform the public on subjects within our expertise;
- Advocate strategies to improve individual and public health by communicating with government, healthcare organizations, and industry;
- Work with society to establish a just, effective, and efficient distribution of healthcare resources;
- Provide necessary surgical care without regard to gender, race, disability, religion, social status, or ability to pay; and
- Participate in educational programs addressing professionalism.

places the responsibility to serve (care for) others above self-interest and reward [see *Sidebar* Elizabeth Blackwell: A Model of Professionalism⁸].

Regrettably, examples of unprofessional behavior exist. An excerpt from a note from a third-year medical student to the core clerkship director reads as follows: "I have seen attendings make sexist, racist jokes or remarks during surgery. I have met residents who joke about deaf patients and female patients with facial hair. [I have encountered] teams joking and counting down the days until patients die" (personal communication, 2004). This kind of exposure to unprofessional conduct and language can influence young people negatively, and it must change.

Most of us went to medical school because we wanted to help and care for people who are ill. This genuine desire to care is unambiguously apparent in the vast majority of personal statements that medical students prepare as part of their application process. To quote William Osler, "You are in this profession as a calling, not as a business; as a calling which extracts from you at every turn self-sacrifice, devotion, love and tenderness to your fellow man. We must work in the missionary spirit with a breath of charity that raises you far above the petty jealousies of life."⁹ To keep medicine a calling, we must explicitly incorporate into the meaning of professionalism those nontechnical practices, habits, and attributes that the compassionate, caring, and competent physician exemplifies. We must remind ourselves that a true professional places service to the patient above self-interest and above reward.

One of the core tenets of professionalism is being consistently respectful not only toward our patients and their families but also toward our colleagues and other health care team members. Although no one would argue with this in principle, there are many factors that challenge our ability to hold true to this precept, including poor interpersonal communication skills, lack of training in conflict resolution, resource constraints, and cultural tradition.

Given that professionalism is so multifaceted, it is not surprising that various important professional values may

conflict with one another, creating tension sometimes internally and at other times between various groups. For example, the patient may want a specific treatment that is not yet supported by evidence but may be of benefit. Meeting the patient's expectations and needs may directly conflict with the expectation that we are advocates for "efficient distribution of health care resources." Another direct challenge to several professionalism obligations is trying to balance the important adherence to the duty hours mandate with the equally important value of continuity of care.¹⁰

The underpinning of medicine as a compassionate, caring profession is the doctor-patient relationship, a relationship that has become jeopardized and sometimes fractured over the past decade. Our individual perceptions of what this relationship is and how it should work will inevitably have a great impact on how we approach the care of our patients.²

The view of the physician-patient relationship as a covenant does not demand devotion to medicine to the exclusion of other responsibilities and is not inconsistent with the fact that medicine is also a science, an art, and a business.² Nevertheless, in our struggle to remain viable in a health care environment that has become a commercial enterprise, efforts to preserve market share cannot take precedence over the provision of care that is grounded in charity and compassion. It is exactly for this reason that medicine always will be, and should be, a relationship between people. To fracture that relationship by exchanging a covenant based on charity and compassion for a contract based solely on the delivery of goods and services is something none of us would want for ourselves. The nature of the healing relationship is itself the foundation of the special obligations of physicians as physicians.²

Translation of Theory into Practice

It is encouraging to note that many instances of unprofessional conduct that once were routinely overlooked—such

Elizabeth Blackwell: A Model of Professionalism⁸

Elizabeth Blackwell was born in England in 1821, the daughter of a sugar refiner. When she was 10 years old, her family emigrated to New York City. Discovering in herself a strong desire to practice medicine and care for the underserved, she took up residence in a physician's household, using her time there to study using books in the family's medical library.

As a young woman, Blackwell applied to several prominent medical schools but was snubbed by all of them. After 29 rejections, she sent her second round of applications to smaller colleges, including Geneva College in New York. She was accepted at Geneva—according to an anecdote, because the faculty put the matter to a student vote, and the students thought her application a hoax. She braved the prejudice of some of the professors and students to complete her training, eventually ranking first in her class. On January 23, 1849, at the age of 27, Elizabeth Blackwell became the first woman to earn a medical degree in the United States. Her goal was to become a surgeon.

After several months in Pennsylvania, during which time she became a naturalized citizen of the United States, Blackwell traveled to Paris, where she hoped to study with one of the leading French surgeons. Denied access to Parisian hospitals because of her gender, she enrolled instead at La Maternité, a highly regarded midwifery school, in the summer of 1849. While attending to a child some 4 months after enrolling, Blackwell inadvertently spattered some pus from the child's eyes into her own left eye. The child was infected with gonorrhea, and Blackwell contracted a severe case of ophthalmia neonatorum, which later necessitated the removal of the infected eye. Although the loss of an eye made it impossible for her to become a surgeon, it did not dampen her passion for becoming a practicing physician.

By mid-1851, when Blackwell returned to the United States, she was well prepared for private practice. However, no male doctor would even consider the idea of a female associate, no matter how well trained. Barred from practice in most hospitals, Blackwell founded her own infirmary, the New York Infirmary for Indigent Women and Children, in 1857. When the American Civil War began, Blackwell trained nurses, and in 1868 she founded a women's medical college at the Infirmary so that women could be formally trained as physicians. In 1869, she returned to England and, with Florence Nightingale, opened the Women's Medical College. Blackwell taught at the newly created London School of Medicine for Women and became the first female physician in the United Kingdom Medical Register. She set up a private practice in her own home, where she saw women and children, many of whom were of lesser means and were unable to pay. In addition, Blackwell mentored other women who subsequently pursued careers in medicine. She retired at the age of 86.

In short, Elizabeth Blackwell embodied professionalism in her work. In 1889 she wrote, "There is no career nobler than that of the physician. The progress and welfare of society is more intimately bound up with the prevailing tone and influence of the medical profession than with the status of any other class."

as mistreating medical students, speaking disrespectfully to coworkers, and fraudulent behavior—are now being dealt with. Still, from time to time, an incident is made public that makes us all feel shame. In March 2003, the *Seattle Times* carried a story about the chief of neurosurgery at the University of Washington, who pleaded guilty to a felony charge of obstructing the government's investigation and admitted that he asked others to lie for him and created an atmosphere of fear in the neurosurgery department.¹¹ According to the US Attorney in Seattle, University of Washington employees destroyed reports revealing that university doctors submitted inflated billings to Medicare and Medicaid. The department chair lost his job, was barred from participation in Medicare, and, as part of his plea bargain, had to pay a \$500,000 fine, perform 1,000 hours of community service,

and write an article in a medical journal about billing errors. The university spent many millions in legal fees and eventually settled the billing issues with the federal government for one of the highest Physicians at Teaching Hospitals (PATH) settlements ever.

Fortunately, such extreme cases of unprofessionalism are quite uncommon. Nevertheless, there are numerous reports in the literature of other types of unprofessional behavior, such as disruptive behavior,⁷ that can lead to patient safety risks.^{12–14} To this end, The Joint Commission has mandated that all of our hospitals have zero tolerance for disruptive behavior. Regardless of the practice setting, it remains our responsibility as professionals to prevent such behaviors from developing and from being reinforced. A study published in 2004 demonstrated an association between displays of unprofessional behavior in medical school and subsequent disciplinary action by a state medical board.¹⁵ The authors concluded that professionalism is an essential competency that students must demonstrate to graduate from medical school. Who could disagree? Yet we know that throughout our careers, there will be challenges, both personal and external, to our consistently behaving professionally.

In addition to the reports recounting acts of unprofessional behavior, various publications describing methods of teaching and assessing professionalism have begun to appear in the past few years.^{16,17} As an example, Kumar and colleagues found that using ACS case-based multimedia materials enhanced the ability of residents to recognize and discuss matters related to professional behavior.¹⁸ Surgical residents who viewed these materials scored higher on an assessment tool than did residents with the same level of experience who did not use the materials. An additional encouraging finding was that residents of all years were able to define the components of professionalism. In another publication, Gauger and colleagues described an evaluation instrument used to evaluate residents with respect to the aspects of professionalism.¹⁹ They divided the concept of professionalism into 15 domains and modified a standard resident evaluation form to assess the faculty's perception of resident performance in each domain. This evaluation tool proved to be internally consistent, but in the absence of any other gold standard tools with which to compare it, its validity could not be determined.

Hickson developed a system to monitor patient complaint data and use this to improve the behavior of individual physicians.²⁰ Others have developed 360° assessment tools to give feedback to physicians regarding how their professionalism skills are perceived by their team members.²¹

Assessment tools and formal courses alone are not enough to support the significant adaptive challenge²² that is involved in maintaining a culture of professionalism.¹⁰ Several authors have argued for a nuanced approach to supporting professional behaviors—one that acknowledges that professionalism is not a fixed trait but rather a set of developmental skills that need to be continuously taught, role-modeled, and reflected on throughout one's career.²³ Understanding that professional behavior is contextual and situation dependent is crucial to developing programs to support professionalism.

The Future of Surgical Professionalism

It is often subtly implied—or even candidly stated—that no matter how well we adjust to the changing health care

environment, the practice of surgery will never again be quite as rewarding as it once was. This need not be the case. The ongoing advances in surgical technology, the increasing opportunities for community-based surgeons to enrol their patients into clinical trials, the growing emphasis on lifelong learning, and the increased focus on teamwork and shared responsibility are factors that not only help satisfy social and organizational demands for quality care but also are in the best interest of our patients.

In the near future, maintenance of certification for surgeons will involve much more than taking an examination every decade. The ACS is taking the lead in helping to develop new measures of competence. Whatever specific form such measures may take, displaying professionalism and living up to a set of uncompromisable core values²⁴ will always be central indicators of the performance of the individual surgeon and the integrity of the discipline of surgery as a whole.

Although surgeons vary enormously with respect to personality, practice preferences, areas of specialization, and style of relating to others, they all have one role in common: that of healer. Indeed, it is the highest of privileges to be able to care for the sick. As the playwright Howard Sackler once wrote, "To intervene, even briefly, between our fellow creatures and their suffering or death, is our most authentic answer to the question of our humanity."²⁵ Inseparable from this privilege is a set of responsibilities that are not to be taken lightly: a pledge to offer our patients the best care possible and a commitment to teach and advance the science and practice of medicine. Commitment to the practice of patient-centered, high-quality, cost-effective care is what gives our work meaning and provides us with a sense of purpose.²⁶ As surgeons, we must participate actively in the current evolution of integrated health care. By doing so, we help build our own future.

Jo Shapiro, MD, FACS, or their significant other, has disclosed a potential conflict of interest as follows: grants and/or salary by Health Dialog

2 PERFORMANCE MEASUREMENT IN SURGERY

Justin B. Dimick MD, MPH, and John D. Birkmeyer MD

With growing recognition that the quality of surgical care varies widely, good measures of performance are in high demand. Patients and their families are looking to make informed decisions about where and from whom to get their surgical care.¹ Employers and payers need measures on which to base their contracting decisions and pay-for-performance initiatives.² Finally, clinical leaders need measures that can help them identify “best practices” and guide their quality improvement efforts. An ever-broadening array of performance measures is being developed to meet these different needs.

However, considerable uncertainty remains about which measures are most useful for measuring surgical quality. Current measures are remarkably heterogeneous, encompassing different elements of health care structure, process of care, and patient outcomes. Although each of these three types of performance measures has unique strengths, each is also associated with conceptual, methodological, and/or practical problems. The baseline risk and frequency of the procedure are obviously important considerations in weighing the strengths and weaknesses of different measures.³ So too is the underlying purpose of performance measurement. Measures that work well when the primary intent is to steer patients to the best hospitals or surgeons (selective referral) may not be optimal for quality improvement purposes and vice versa.

Expanding on other recent reviews of performance measurement,^{3–5} this chapter provides an overview of measures commonly used to assess surgical quality, considers their main strengths and limitations, and closes with recommendations for selecting the optimal quality measure [see Table 1].

Overview of Current Measures

The number of performance measures that have been developed for the assessment of surgical quality is already large and continues to grow. Many surgical quality indicators are already used in hospital accreditation, pay-for-performance, or public reporting efforts. Over the past few years, the National Quality Forum (NQF) has emerged as the leading organization endorsing quality measures. Many influential organizations, including the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) and the Centers for Medicare and Medicaid Services (CMS), rely on the endorsement of the NQF before applying a measure to practice. The number of measures relevant to surgery that have been endorsed by the NQF has grown rapidly.

Although the NQF is the central organization for evaluating quality measures, many organizations develop candidate measures and submit them for endorsement. The Agency for Healthcare Research and Quality (AHRQ) has focused primarily on quality measures that take advantage of readily available administrative data, such as the hospital discharge data sets comprising the Healthcare Cost and Utilization Project (HCUP) [see Table 2]. Because little information on process of care is available in these data sets, these measures are mainly structural (e.g., hospital procedure volume) or outcome based (e.g., risk-adjusted mortality).

The Leapfrog Group (<http://www.leapfroggroup.org>), a coalition of large employers and purchasers, has developed perhaps the most visible set of surgical quality indicators for its value-based purchasing initiative. The organization's original standards focused exclusively on procedure volume but later expanded its standards to include selected process variables (e.g., the use of beta blockers in patients undergoing abdominal aortic aneurysm repair) and outcome measures, such as mortality. Most recently (2010), the Leapfrog Group began using a composite of operative mortality and hospital volume, the so-called “Survival Predictor,” as the primary measure for its evidence-based hospital referral initiative. Such composite measures are discussed further below.

Several surgical professional organizations have played a large part in developing many of the quality measures endorsed by the NQF. The Society of Thoracic Surgeons (STS) has been a leader in the development of quality measures for cardiac and thoracic procedures [see Table 3 and Table 4]. These measures include the structure, process, and outcomes of cardiac surgical care. In addition, the STS recently developed a composite measure that combines all of these domains of quality into a single hospital rating. The National Surgical Quality Improvement Program (NSQIP) has also developed measures for colectomy, lower extremity bypass, and elderly surgical patients [see Table 3 and Table 4]. Finally, the Society for Vascular Surgery (SVS) has acted as the steward for measures of process of care for carotid endarterectomy [see Table 4].

Structural Measures of Quality

Health care structure reflects the setting or system in which care is delivered. Many structural measures describe hospital-level attributes, such as the physical plant and resources or staff coordination and organization (e.g., nurse-to-bed ratios, designation as a Level I trauma center). Other structural measures reflect attributes associated with the relative expertise of individual physicians (e.g., board certification, subspecialty training, or procedure volume).

STRENGTHS

From a measurement perspective, structural measures of quality have several attractive features. First, many of these

Financial disclosure information is located at the end of this chapter before the references.

Table 1 Primary Strengths and Limitations of Structure, Process, and Outcome Measures

	<i>Structure</i>	<i>Process</i>	<i>Outcomes</i>
Examples	Procedure volume, intensivist-managed ICUs	Appropriate use of prophylactic antibiotics	Risk-adjusted mortality rates for CABG from state or national registries
Strengths	Expedient, inexpensive Efficient—one measure may relate to several outcomes For some procedures, better predictor of subsequent performance than other measures	Reflect care that patients actually receive—buy-in from providers Directly actionable for quality improvement activities Do not need risk adjustment for many measures	Face validity Measurement alone may improve outcomes (i.e., Hawthorne effect)
Limitations	Limited number of measures Generally not actionable Do not reflect individual performance, considered unfair by providers	Many measures hard to ascertain with existing databases Variable extent to which process measures link to important patient outcomes Lack of high leverage, procedure-specific processes	Sample size constraints Expense of clinical data collection Concerns about risk adjustment with administrative data

CABG = coronary artery bypass grafting; ICU = intensive care unit.

Table 2 Surgical Performance Measures that Apply to Multiple Surgical Procedures Endorsed by the National Quality Forum

<i>Diagnosis or Procedure</i>	<i>Performance Measure</i>	<i>Steward</i>
All surgical procedures	Appropriate antibiotic prophylaxis (selection, timing, and duration)	AMA
	Hair clipping prior to surgery	CMS
	Appropriate venous thromboembolism prophylaxis	AMA/CMS
	Perioperative temperature management	CMS
	Preoperative beta blockers continued after surgery	CMS
	Urinary catheter removed postoperative day 2	CMS
	Risk-adjusted surgical mortality or major complications in elderly patients	ACS/NSQIP
	Accidental puncture or laceration	AHRQ
	Iatrogenic pneumothorax	AHRQ
	Wound dehiscence	AHRQ
	Postoperative respiratory failure	AHRQ
	Failure to rescue	AHRQ
	Postoperative venous thromboembolism	AHRQ

Pediatric surgery	Risk-adjusted mortality in neonates undergoing noncardiac surgery	CHOP

ACS = American College of Surgeons; AHRQ = Agency for Healthcare Research and Quality; AMA = American Medical Association; CDC = Centers for Disease Control and Prevention; CHOP = Children's Hospital of Pennsylvania; CMS = Centers for Medicare and Medicaid Services; JCAHO = Joint Commission on Accreditation of Healthcare Organizations; NSQIP = National Surgical Quality Improvement Program; STS = Society of Thoracic Surgeons.

measures are strongly related to patient outcomes. For example, with esophagectomy and pancreatic resection, operative mortality rates at very high-volume hospitals are as much as 10% lower, in absolute terms, than at lower-volume centers.^{6,7} In some instances, structural measures such as procedure volume are more predictive of subsequent hospital performance than any known processes of care or direct mortality measures⁸ [see Figure 1].

A second advantage is efficiency. A single structural measure may be associated with numerous outcomes. For example, with some types of cancer surgery, hospital or

surgeon procedure volume is associated not only with lower operative mortality but also with lower perioperative morbidity and higher late survival rates.^{9–11} Intensivist model intensive care units are linked to shorter length of stay and reduced resource use, as well as lower mortality.^{12,13}

The third and perhaps most important advantage of structural variables is expediency. Many can be assessed easily with readily available administrative data. Although some structural measures require surveying hospitals or providers, such data are much less expensive to collect than measures requiring patient-level information.

Table 3 Surgical Performance Measures Endorsed by the National Quality Forum that Apply to Specific Cardiac and Vascular Procedures

<i>Diagnosis or Procedure</i>	<i>Performance Measure</i>	<i>Steward</i>
Coronary artery bypass grafting	Hospital volume	STS
	Risk-adjusted mortality rate	STS
	Postoperative renal failure	STS
	Internal mammary artery use	STS
	Preoperative beta blockade	STS
	Postoperative glucose controlled by 6 am the day after surgery	JCAHO
	STS composite measure	STS
	Reoperation for tamponade, bleeding, or other cardiac reason	STS
	Antiplatelet therapy at discharge	STS
	Beta-blocker therapy at discharge	STS
	Antilipid therapy at discharge	STS
	Deep sternal wound infection rate	STS
	Prolonged intubation	STS
	Stroke	STS

	Risk-adjusted mortality rates	AHRQ
Abdominal aneurysm repair	Hospital volume	AHRQ
	Risk-adjusted mortality rates	AHRQ
Lower extremity bypass	Risk-adjusted mortality or major complications	CMS
Carotid endarterectomy	Perioperative antiplatelet therapy	SVS
	Patch closure of arteriotomy	SVS

AHRQ = Agency for Healthcare Research and Quality; CMS = Center for Medicare and Medicaid Services; JCAHO = Joint Commission on Accreditation of Healthcare Organizations; STS = Society of Thoracic Surgeons.

DISADVANTAGES OF STRUCTURAL VARIABLES

Among the downsides, there are relatively few structural measures that may be potentially useful as quality indicators. Second, in contrast to process measures, most structural measures are not readily actionable. For example, a small hospital can increase the number of surgical patients receiving antibiotic prophylaxis but cannot readily make itself a high-volume center. Thus, although selected structural measures may be useful for selective referral initiatives, they have limited value for quality improvement purposes.

Finally, structural measures generally describe groups of hospitals or providers with better performance but do not adequately discriminate performance among individuals. For example, in aggregate, high-volume hospitals have much lower mortality rates than lower-volume centers for pancreatic resection. However, some individual high-volume hospitals may have high mortality rates. Although difficult to confirm empirically (for sample size reasons), some low-volume centers may have excellent performance.¹⁴ For this reason, structural measures are viewed as “unfair” by many providers.

Process of Care Measures

Processes of care are the clinical interventions and services provided to patients. Process measures have long been the predominant quality indicators for both inpatient and outpatient medical care, and their popularity as quality measures for surgical care is growing rapidly. Perhaps the best example of the trend toward using process measures is the CMS Surgical Care Improvement Program (SCIP). The SCIP mandates all hospitals to collect and publicly report process measures related to prevention of surgical site infections (SSIs), postoperative cardiac events, venous thromboembolism (VTE), and respiratory complications.

STRENGTHS

Given that processes of care reflect the care that physicians deliver, they have face validity and enjoy greater buy-in from providers. They are usually directly actionable and thus good substrate for quality improvement activities.

Although risk adjustment may be important for outcomes, it is not required for many process measures. For example, when measuring appropriate prophylaxis

Table 4 Surgical Performance Measures Endorsed by the National Quality Forum that Apply to Specific General Surgical Procedures

<i>Diagnosis or Procedure</i>	<i>Performance Measure</i>	<i>Steward</i>
Esophageal resection	Hospital volume	AHRQ
	Risk-adjusted mortality	STS/AHRQ
	Preoperative assessment of performance status	STS
Pancreatic resection	Hospital volume	AHRQ
	Risk-adjusted mortality rates	AHRQ
Colon resection	Risk-adjusted mortality or major complications	ACS/NSQIP
	For cancer, adjuvant chemotherapy within 4 months for lymph node-positive disease	ACS
	For cancer, at least 12 lymph nodes are harvested	ACS
	For cancer, complete pathology reporting	ACS
Melanoma	Coordination of care	AMA
Breast cancer	Post-breast conservation radiation	ACS
	Appropriate axillary staging	Intermountain Healthcare
	Adjuvant hormonal therapy in receptor-positive patients	ACS
	Adjuvant chemotherapy in appropriate patients	ACS
	Needle biopsy to establish diagnosis of cancer precedes surgical excision/resection	ACS
Appendicitis	Proportion with perforation	AHRQ
	Incidental appendectomy in the elderly	AHRQ

ACS = American College of Surgeons; AHRQ = Agency for Healthcare Research and Quality; AMA = American Medical Association; NSQIP = National Surgical Quality Improvement Program; STS = Society of Thoracic Surgeons.

against postoperative VTE, one of the SCIP measures, it is not necessary to account for patient differences in risk. Given that virtually all patients undergoing open abdominal surgery should be offered some form of prophylaxis, there is little need to collect detailed clinical data about illness severity for the purpose of risk adjustment.

Finally, process measures are generally less constrained by sample size problems than direct outcome measures. Whereas important outcomes (e.g., perioperative death) are relatively rare, most targeted process measures are relevant to a larger proportion of patients. Moreover, because they generally target aspects of general perioperative care, process measures can often be assessed on patients undergoing numerous different procedures, increasing sample sizes and measurement precision.

LIMITATIONS

At the current time, a major limitation of process measures is the lack of a reliable data infrastructure for ascertaining them. Administrative data sets lack the requisite clinical detail and specificity for this purpose. Measurement systems based on clinical data, including that of the NSQIP,¹⁵ focus on patient characteristics and outcomes and do not collect information on process of care. Presently, pay-for-performance programs rely on self-reported information from hospitals, but the reliability of such data is uncertain (particularly when reimbursement is at stake).

Even if this limitation were overcome, a second limitation remains to be considered—namely, that process variables are limited in their ability to explain observed variations in

mortality. A growing body of empirical data supports this statement. Most of the data come from the literature on medical diagnoses (e.g., acute myocardial infarction), where the link between process and outcome is much stronger than it is in surgery.¹⁶⁻¹⁸ For example, the JCAHO/CMS process measures for acute myocardial infarction explained only 6% of the observed variation in risk-adjusted mortality for this condition.¹⁷

There is reason to believe that existing process measures explain very little of the variation in important outcomes in surgery. First, most process measures currently used in surgery relate to secondary rather than primary outcomes. For example, although the value of antibiotic prophylaxis in reducing the risk of superficial SSI should not be underestimated, this process is not among the most important adverse events of major surgery (including death). Second, process measures in surgery often relate to complications that are very rare. For example, there is a consensus that prophylaxis for VTE is necessary and important. Accordingly, the SCIP measures, endorsed by the NQF, include the use of appropriate prophylaxis. However, pulmonary embolism is very uncommon; therefore, improving adherence to these measures will not avert many deaths.

Several recent empirical studies on the relation between SCIP processes and patient outcomes support this assertion. For example, Nicholas and colleagues examined the relation between hospital SCIP process compliance and risk-adjusted rates of mortality, thromboembolism, and surgical infection.¹⁹ Despite wide variation in process compliance, there was no association between adherence to SCIP measures

Figure 1 Relative ability of historical (2005–2006) measures of hospital volume and risk-adjusted mortality to predict subsequent (2007–2008) risk-adjusted mortality in US Medicare patients. (a) Pancreatic resection. (b) Esophageal resection.

and any of these risk-adjusted outcomes. Until a better understanding is achieved regarding which details account for variations in the most important complications, especially those adverse events leading to death, process measures will continue to be of limited usefulness in surgical quality improvement.

Direct Outcome Measures

Direct outcome measures reflect the end result of care, from a clinical perspective or as judged by the patient. Although mortality is by far the most commonly used measure in surgery, other outcomes that could be used as quality indicators include complications, hospital readmission, and a variety of patient-centered measures of satisfaction or health status.

There are several ongoing, large-scale initiatives involving direct outcomes assessment in surgery. Proprietary health care rating firms (e.g., Healthgrades) and state agencies are assessing risk-adjusted mortality rates using Medicare or state-level administrative data sets. However, most of the current interest in outcomes measurement involves large clinical registries. Cardiac surgery registries in New York, Pennsylvania, and a growing number of other states are perhaps the visible examples. At the national level, the STS and the American College of Cardiology (ACC) have implemented systems for tracking morbidity and mortality with cardiac surgery and percutaneous coronary interventions, respectively. Although most outcomes measurement efforts have been procedure specific (and largely limited to cardiac procedures), the NSQIP of the American College of Surgeons (ACS) assesses hospital-specific morbidity and mortality rates aggregated across surgical specialties and procedures.¹⁶

STRENGTHS

Direct outcome measures have at least two major advantages. First, direct outcome measures have obvious face validity and thus are likely to get the greatest “buy-in” from hospitals and surgeons. Second, outcomes measurement alone may improve performance—the so-called Hawthorne effect. For example, surgical morbidity and mortality rates in Veterans Affairs’ hospitals have fallen dramatically since implementation of NSQIP in 1991.¹⁵ No doubt many surgical leaders at individual hospitals made specific organizational or process improvements after they began receiving feedback on their hospitals’ performance. However, it is very unlikely that even a full inventory of these specific changes would explain such broad-based and substantial improvements in morbidity and mortality rates.

DISADVANTAGES OF DIRECT OUTCOME MEASURES

Hospital- or surgeon-specific outcome measures are severely constrained by small sample sizes. For the large majority of surgical procedures, very few hospitals (or surgeons) have sufficient adverse events (numerators) and cases (denominators) for meaningful, procedure-specific measures of morbidity or mortality. For example, Dimick and colleagues used data from the Nationwide Inpatient Sample to study seven procedures for which mortality rates have been advocated as quality indicators by the AHRQ.²⁰ For six of these procedures, a very small proportion of US

hospitals had adequate caseloads to rule out a mortality rate twice the national average. Although identifying poor quality outliers is an important function of outcomes measurement, focusing on this goal alone significantly underestimates problems with small sample sizes. Discriminating among individual hospitals with intermediate levels of performance is even more difficult.

Other limitations of direct outcomes assessment depend on whether outcomes are being assessed from administrative data or clinical information abstracted from medical records. For outcomes measurement based on clinical data, the major problem is expense. For example, it costs over \$100,000 annually for a private sector hospital to participate in the NSQIP.

With administrative data, the adequacy of risk adjustment remains a major concern. High-quality risk adjustment may be essential for outcome measures to have face validity with providers. It may also be useful for discouraging gaming, for example, hospitals or providers avoiding high-risk patients to optimize their performance measures. However, it is not clear how much the scientific validity of outcome measures is threatened by imperfect risk adjustment with administrative data. Although administrative data lack clinical detail on many variables related to baseline risk,^{21–24} it is not clear to what extent case mix varies systematically across hospitals or surgeons. Among patients undergoing the same surgical procedure, there is often surprisingly little variation. For example, we examined risk-adjusted mortality rates for hospitals performing coronary artery bypass grafting in New York State, as derived from their clinical registries.²⁵ Unadjusted and adjusted hospital mortality rates were nearly identical in most years (correlations exceeding 0.90). Moreover, hospital rankings based on unadjusted and adjusted mortality were equally useful in predicting subsequent hospital performance.

Matching the Measure to the Purpose

Performance measures will never be perfect. Over time, analytical methods will be refined. Access to higher-quality data may improve with the addition of clinical elements to administrative data sets or broader adoption of electronic medical records. However, some problems with performance measurement, including sample size limitations, are inherent and not fully correctable. Thus, clinical leaders, patient advocates, payers, and policy makers will not escape having to make decisions about when imperfect measures are good enough to act upon.

A measure should be implemented only with the expectation that acting will result in a net improvement in health quality. Thus, the direct benefits of implementing a particular measure cannot be outweighed by the indirect harms. Unfortunately, these benefits and harm are often difficult to measure and heavily influenced by the specific context and who—patients, payers, or providers—is doing the accounting. For this reason, there is no simple answer for where to “set the bar.”

It is important to ensure a good match between the performance measure and the primary goal of measurement. The right measure depends on whether the underlying goal is (1) quality improvement or (2) selective referral—directing patients to higher-quality hospitals and/or providers.

Although many pay-for-performance initiatives have both goals, one often predominates. For example, the ultimate objective of CMS's pay-for-performance initiative with prophylactic antibiotics is improving quality at all hospitals—not directing patients to those centers with high compliance rates. Conversely, although it may indirectly incentivize quality improvement, the Leapfrog Group's efforts in surgery are primarily aimed at getting patients to hospitals likely to have the best outcomes (selective referral).

For quality improvement purposes, a good performance measure—most often a process of care variable—must be actionable. Measurable improvements in the given process should translate to clinically meaningful improvements in patient outcomes. Although quality improvement activities are rarely “harmful,” their major downsides relate to their opportunity cost. Initiatives hinged on bad measures siphon away resources (e.g., time and focus of physicians and other staff) from more productive activities.

With selective referral, a good measure will steer patients to better hospitals or physicians (or away from worse ones). As one basic litmus test, a measure based on prior performance should reliably identify providers likely to have superior performance now and in the future. At the same time, an ideal measure would not incentivize perverse behaviors (e.g., surgeons doing unnecessary procedures to meet a specific volume standard) or negatively affect other domains of quality (e.g., patient autonomy, access, and satisfaction).

Measures that work well for quality improvement may not be particularly useful for selective referral, and vice versa. For example, appropriate use of perioperative antibiotics in surgical patients is a good measure for quality improvement. This process of care is clinically meaningful, linked to lower risks of SSIs, and directly actionable. Conversely, antibiotic use would not be particularly useful for selective referral purposes. It is unlikely that patients would use this information to decide where to have surgery. More importantly, surgeons with high rates of appropriate antibiotic use may not necessarily do better with more important outcomes (e.g., mortality). Physician performance with one quality indicator is often poorly correlated with other indicators for the same or other clinical conditions.²⁶

As a counter example, the two main quality indicators for pancreatic cancer—hospital volume and operative mortality—are very informative in the context of selective referral. Patients would markedly improve their odds of surviving surgery by selecting hospitals highly ranked by either measure [see Figure 1]. However, neither measure would be particularly useful for quality improvement purposes. Volume is not readily actionable; mortality rates are too unstable at the level of individual hospitals (because of small sample size problems) to identify top performers, identify best practices, or evaluate the effects of improvement activities.

Many believe that a good performance measure must discriminate performance at the individual level. From the provider perspective in particular, a “fair” measure must reliably reflect the performance of individual hospitals or physicians. Unfortunately, as described earlier, small case-loads (and sometimes case-mix variation) conspire against this objective for most procedures. Patients, however, should value information that improves their odds of good

outcomes on average. Many measures meet this latter interest while failing on the former.

For example, Krumholz and colleagues used clinical data from the Cooperative Cardiovascular Project to assess the usefulness of Healthgrades' hospital ratings for acute myocardial infarction (based primarily on risk-adjusted mortality rates from Medicare data).²⁷ Relative to one-star (worst) hospitals, five-star (best) hospitals had significantly lower mortality (16% versus 22%, $p < .001$) after risk adjustment with clinical data. They also discharged significantly more (appropriate) patients on aspirin, beta blockers, and angiotensin-converting enzyme (ACE) inhibitors, all recognized quality indicators. However, the Healthgrades' ratings poorly discriminated among any two individual hospitals. In only 3% of head-to-head comparisons did five-star hospitals have statistically lower mortality rates than one-star hospitals.

Thus, some performance measures that clearly identify groups of hospitals or providers with superior performance may be limited in their ability to discriminate individual hospitals from one another. There may be no simple solution to resolving the basic tension implied by performance measures that are unfair to providers yet informative for patients. However, it underscores the importance of being clear about both the primary purpose (quality improvement or selective referral) and whose interests are receiving top priority (provider or patient).

Future of Performance Measurement

Although great progress has been made, the science of surgical quality measurement is still in its infancy. Several barriers must be overcome before performance measures can be optimally used to improve patient care. Perhaps the biggest barrier is the lack of an accurate and affordable measurement infrastructure. One practical solution that may reduce the expense of detailed data collection with clinical registries is to create hybrid systems that join data elements from administrative and clinical data sets. Although administrative data are criticized for their lack of accuracy in identifying coexisting diseases, they can reliably identify the type of procedure performed, certain demographic variables (e.g., age, gender, and race), and some outcome variables (e.g., vital status, discharge to a skilled nursing facility, and length of stay). This set of variables could then be linked to a limited set of clinical risk factors that would allow robust risk adjustment. This solution will be even more attractive as administrative data come to contain more accurate information (e.g., present-on-admission codes to distinguish complications from coexisting problems).²⁸

In addition to improving the efficiency of data collection, it would be worthwhile to rethink how existing registries are designed so as to make them less expensive and more useful. For example, although the ACS-NSQIP is in a key position to become the leading measurement platform for surgical quality improvement, several changes could be made to ensure its success.²⁹ First, the burden of data collection could be reduced; this would substantially decrease the costs of participating. The number of data elements could be reduced by creating more parsimonious risk adjustment models.³⁰ Second, the sampling strategy could be changed to sample 100% of the most important operations; this change

would allow assessment of procedure-specific outcomes. Ultimately, participating hospitals would need procedure-specific outcome data to target specific operations for improvement. Third, clinical processes of care could be added to the data collection process; this would allow hospitals to respond to national pay-for-performance mandates and to provide more actionable quality measures. This last change would require the ACS-NSQIP to manifest a level of flexibility that it has not exhibited to date. With the flexibility to change data measurement periodically, the ACS-NSQIP would not only be able to add other measures that are used in national mandates (e.g., SCIP) but also to evaluate their importance.

One of the biggest limitations of surgical quality measurement is the statistical noise from the small sample sizes at most hospitals. An emerging technique, reliability adjustment, directly addresses the problem of statistical noise. This technique, based on hierarchical modeling, quantifies and subtracts statistical noise from the measurement process.³¹ Essentially, it “shrinks” a provider’s performance back toward average, unless they deviate to such an extreme that it is safe to assume that they are truly different. In this way, it gives providers the benefit of the doubt. For example, Figure 2 shows the risk-adjusted mortality and morbidity rates for colon resection in 20 ACS-NSQIP hospitals before and after reliability adjustment. Prior to reliability adjustment, rates of mortality and morbidity vary greatly across these hospitals. After reliability adjustment, however, the “noise” has been removed and rates of morbidity and mortality vary much less, yielding a range of performance that is clinically more realistic. These reliability-adjusted mortality rates are much more accurate at capturing true performance, as assessed by their ability to predict future performance.

Despite increasing use in other fields, such as ambulatory care, reliability adjustment is only beginning to find applications in surgery. Perhaps the most prominent example is the Massachusetts cardiac surgery report card, which publishes reliability-adjusted mortality rates for each hospital. This approach will also likely be applied to general and vascular

surgery, as described with other changes in a recent “blueprint” for a new NSQIP, discussed above. As the advantages of this technique become more widely known, there is no doubt that it will become the standard technique for reporting risk-adjusted outcomes.

Another barrier to improving surgical performance is the lack of good global measures of performance. With the proliferation of pay-for-performance pilot programs, various stakeholders have been confronted with the problem of how to make sense of multiple competing measures of quality. Most have responded by combining multiple domains to create a composite measure of performance. The Premier/CMS Hospital Quality Incentive Demonstration uses a composite of process and outcome as a quality measure for coronary artery bypass surgery. The STS’s Task Force on Quality Measurement advocates a composite score based on a set of outcome and process measures endorsed by the NQF.³² In these composite approaches, the different measures are essentially weighted equally, with no empirical determination of which ones are the most important. There are, however, emerging techniques that use empirically derived weighting to create a composite score that optimally predicts future mortality for high-risk surgery.³³ As such methods become more fully developed, composite measures will no doubt continue to gain popularity.

Given that most existing quality improvement efforts focus on optimizing measurement of technical quality, it is important not to lose sight of the fact that many quality concerns arise upstream from the operation itself—that is, with the decision to operate in the first place. Wide variations in the use of surgery have long been recognized. Some of these variations are attributable to differences in disease prevalence and physician practice style. Some, however, arise from overuse, underuse, or misuse of surgical management. For a full accounting of surgical quality, it will be necessary to develop reliable means of measuring the appropriateness of surgical treatment and the extent to which patient preferences are incorporated into clinical decisions, in addition to measures assessing how well patients do after surgery.

Financial Disclosures: Dr. Dimick and Dr. Birkmeyer are both equity owners and paid consultants for ArborMetrix, Inc.

Figure 2 Risk-adjusted (a) mortality and (b) morbidity rates for colon resection at individual hospitals before and after adjustment for reliability. Data are from the 2007 American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP).

3 STRATEGIES FOR IMPROVING SURGICAL QUALITY

Nancy J.O. Birkmeyer, PhD

Surgical morbidity and mortality are major public health concerns. At least 1 million surgical patients die, and many times more experience a serious complication each year worldwide.¹ The outcomes of surgery have been shown to differ among providers²⁻⁷ and according to provider attributes such as procedure volume⁸⁻¹⁰ and subspecialty training.¹¹⁻¹³ This variability in the outcomes of surgical procedures has long suggested opportunities to improve the quality of surgical care. For this reason, many large-scale quality improvement efforts target patients undergoing surgery.

Payers, health care policy makers, and surgeons' professional organizations have implemented a range of strategies to improve surgical quality. With selective referral, payers use various methods to try to steer patients to providers that they have deemed to be of higher quality. Pay-for-performance programs, such as the Surgical Care Improvement Project (SCIP), provide incentives for providers' compliance with specific evidence-based processes of perioperative care. Many professional organizations, including the American College of Surgeons National Surgical Quality Improvement Program (NSQIP), have instituted outcomes measurement and feedback programs to stimulate quality improvement at the local level. Regional collaborative quality improvement programs go beyond outcomes measurement and feedback to broad-scale implementation of quality improvement interventions.

These strategies, which we refer to as selective referral, process compliance, outcomes measurement and feedback, and regional collaborative quality improvement, are the current, dominant approaches to surgical quality improvement in the United States. This chapter reviews these strategies and some of the major ongoing initiatives in each [see Table 1]. In addition, the evidence to date for the effectiveness of each of these strategies in improving surgical quality is summarized.

Selective Referral

Selective referral includes strategies that aim to identify and steer patients toward providers with the best results for certain procedures. Payers' selective referral programs may involve the use of tiered health plans and benefits packages that give patients' financial incentives (e.g., lower copayments or monthly premiums) for selecting providers that they have deemed to be of higher quality. Some payers restrict their enrollees' choice of providers to selected Centers of Excellence (COE) for certain high-risk procedures, whereas others simply provide information about approved

COE to their enrollees without restricting choice. Examples of selective referral programs include the Leapfrog Group's Evidence-Based Hospital Referral program, Blue Cross and Blue Shield Association Blue Distinction Centers for Specialty Care, and bariatric surgery COE programs of the American College of Surgeons and the American Society for Metabolic and Bariatric Surgery.

The extent to which selective referral programs result in improvements in surgical quality has been assessed in a number of recent studies. One group of studies has examined whether COE programs successfully identify hospitals with better outcomes. For example, one study investigated whether Medicare patients undergoing major cancer resections (1994 to 1999) at National Cancer Institute (NCI) cancer centers have lower mortality rates than patients at control hospitals matched for procedure volume.¹⁴ NCI cancer centers had significantly lower adjusted surgical mortality rates than control hospitals for four of the six procedures assessed, including colectomy, pulmonary resection, gastrectomy, and esophagectomy. Trends toward lower adjusted operative mortality rates at NCI cancer centers were also observed for cystectomy and pancreatic resection. However, there were no important differences in subsequent 5-year mortality rates between NCI cancer centers and control hospitals for any of the procedures. A subsequent study including Survival, Epidemiology, and End Results (SEER)-Medicare patients from 1999 to 2003 did find improved survival rates for patients undergoing surgery for colorectal cancer at NCI cancer centers compared with other hospitals, reflecting perhaps the difference in time periods between the two studies and/or the ability to control for tumor stage with the data source used in the later study.¹⁵ In bariatric surgery, two studies found that bariatric COE hospitals do not have lower rates of surgical complications than other hospitals.^{16,17}

Two recent studies considered whether selective referral programs have altered referral patterns for high-risk surgery and whether these trends have resulted in improvements in operative mortality with those procedures. One study found that increased market concentration was strongly associated with declining mortality with some high-risk cancer operations [see Figure 1], including pancreatectomy, esophagectomy, and cystectomy.¹⁸ A smaller proportion of mortality improvements could be attributed to market concentration for lung resection, abdominal aortic aneurysm repair, and aortic valve replacement, but trends in market concentration had no role in declining mortality with coronary artery bypass grafting (CABG) and carotid endarterectomy. A study based on data from Washington State found that the proportion of patients undergoing surgery in hospitals meeting the Leapfrog Groups' volume standard had significantly increased for pancreatectomy and esophagectomy, but not aortic aneurysm repair, since

Table 1 Characteristics of Different Strategies for Improving Surgical Quality

	<i>Selective Referral</i>	<i>Process Compliance</i>	<i>Outcomes Measurement and Feedback</i>	<i>Regional Collaborative Quality Improvement</i>
Mechanism	Steer patients to best hospitals or surgeons	Increase compliance with evidence-based processes of care	Spur internal quality improvement with feedback on benchmarked outcomes	Identify and broadly implement best practices
Examples	Leapfrog Group's Evidence-Based Hospital Referral Program Payers' Center of Excellence (COE) programs	Surgical Care Improvement Project (SKIP) Surgical Checklist projects	National Surgical Quality Improvement Program (NSQIP) Society of Thoracic Surgeons (STS) National Cardiac Surgery Database	Northern New England Cardiovascular Disease Study Group Blue Cross and Blue Shield of Michigan/Blue Care Network Value Partnership program
Evidence: pro	Effective for relatively rare procedures with strong evidence linking provider characteristics (e.g., procedure volume) and outcomes	Programs that involve active participation of surgeons and other clinicians (e.g., checklists) may be effective regardless of actual content of intervention	Effective for motivating internal quality improvement efforts among low-performing providers	Improved outcomes in the areas where it has been tried: cardiovascular procedures, other general and vascular surgery, and bariatric surgery
Evidence: con	COE programs based on self-reported, unreliable data not effective in identifying higher-quality providers	Disappointing results for other process compliance interventions	Do not provide guidance for how to improve either to low-performing providers or others	Strategy has not been widely adopted perhaps because expense and complexity and lack of a natural sponsor

implementation of the Leapfrog Groups' Evidence-Based Hospital Referral Program.¹⁹ Although mortality rates tended to be lower for hospitals meeting the volume thresholds, statewide mortality rates did not improve over the time period.¹⁹

Selective referral is arguably the most controversial of the quality improvement strategies discussed in this chapter. Although selective referral strategies are effective in improving outcomes in a number of procedures, they are less useful for many others. This strategy is also highly divisive, with many arguing that providers should be judged by their own clinical outcomes rather than having their outcomes judged by imperfect proxy measures, such as volume.²⁰ Selective

referral is probably best reserved for high-risk procedures where a strong relation between provider structural characteristics (such as procedure volume or subspecialty training) and outcomes has been demonstrated. Selective referral programs should not rely on self-reported and/or unverifiable information to determine which providers have the highest quality.^{16,17,21}

Process Compliance

Another strategy for improving surgical quality is for hospitals to increase their use of evidence-based processes of care. Public and private payers' ongoing pay-for-performance programs, which provide financial incentives for high rates of compliance, best exemplify this strategy. The largest pay-for-performance program targeting surgery is the SCIP, which links Medicare hospital reimbursement to satisfactory adherence to processes for reducing rates of surgical site infection, postoperative cardiac events, venous thromboembolism, and ventilator-associated pneumonia.

SURGICAL CARE IMPROVEMENT PROJECT (SCIP)

The relation between SCIP measure compliance and outcomes has been assessed in a number of studies [see Table 2]. Nicholas and colleagues used national Medicare data to examine whether rates of compliance with the SCIP measures were associated with rates of surgical site infection, venous thromboembolism, or surgical mortality for patients undergoing high-risk cancer or cardiovascular procedures.²² Although process compliance ranged from 53.7% for hospitals in the bottom tercile to 91.4% for hospitals in the top tercile, there was no relation between rates of process compliance and rates of surgical site infection, venous thromboembolism, or surgical mortality overall or for any of

Figure 1 Percent of mortality decline for esophagectomy, pancreatectomy, cystectomy, and lung resection attributable to increases in market concentration, based on 2001 to 2008 national Medicare data.¹⁸

Table 2 Evidence Regarding the Relation between Compliance with Surgical Care Improvement Project (SCIP) Measures and Clinical Outcomes

Study, Year	Data Sources (Year)	Patient Population (n)	SCIP Measure*	Infection	VTE	Mortality
Nicholas et al, 2010 ²²	2000 US hospitals/ Medicare/Hospital Compare (2005–2006)	6 high-risk procedures (325,052)	SCIP INF/VTE- Composite	No	No	No
Ingraham et al, 2010 ²³	200 ACS-NSQIP hospitals/ Hospital Compare (2008)	General and vascular surgery (81,524)	SCIP INF-1 SCIP INF-2 SCIP INF-3 SCIP INF-6	No Yes No No		No No No No
Stulberg et al, 2010 ²⁵	398 Premier Inc. hospitals/ Hospital Compare (2006–2008)	Inpatient surgery (405,720)	SCIP INF-1 SCIP INF-2 SCIP INF-3 SCIP INF-4 SCIP INF-6 SCIP INF-7 SCIP INF-Composite	No No No No No No Yes		
Lehtinen, 2010 ⁴¹	1 ACS-NSQIP hospital (2006–2009)	Gastrointestinal surgery (469)	SCIP INF-10	No		
Pastor, 2010 ⁴²	1 US hospital (2006–2008)	Colorectal surgery (491)	SCIP INF-Composite	No		
Hawn et al, 2008 ²⁶	95 Veterans Affairs hospitals (2005–2006)	Elective orthopedic, colon, and vascular surgery (9,195)	SCIP INF-1	No		
Forbes et al, 2008 ²⁷	1 Canadian hospital (2004–2007)	Major hepatobiliary or colorectal surgery (208)	SCIP INF-Composite	Yes—NS		
Berenguer, 2010 ²⁹	1 ACS-NSQIP hospital (2006–2008)	Colorectal surgery (197)	SCIP INF-Composite			
Hedrick et al, 2007 ²⁸	1 hospital (2000–2005)	Colorectal surgery (307)	SCIP INF-Composite	Yes		

ACS-NSQIP = American College of Surgeons-National Surgical Quality Improvement Program; NS = not statistically significant; VTE = venous thromboembolism.

*SCIP measures: SCIP INF-1: prophylactic antibiotic received within 1 hour prior to surgical incision; SCIP INF-2: prophylactic antibiotic selection for surgical patients; SCIP INF-3: prophylactic antibiotics discontinued within 24 hours after surgery end; SCIP INF-4: cardiac surgery patients with controlled 6 am postoperative blood glucose; SCIP INF-6: surgery patients with appropriate hair removal; SCIP INF-7: colorectal surgery patients with immediate postoperative normothermia; SCIP INF-10: surgery patients with perioperative temperature management; SCIP VTE-1: surgery patients with recommended venous thromboembolism prophylaxis ordered; SCIP VTE-2: surgery patients who received appropriate venous thromboembolism prophylaxis within 24 hours prior to surgery to 24 hours after surgery.

the six procedures individually. Numerous studies have examined the relation between the subset of SCIP measures related to the prevention of surgical site infection (SCIP INF) and clinical outcomes. Of these, one found that just one of the measures (SCIP 2: appropriate antibiotic given) was associated with rates of surgical site infection.²³ Another study found that only SCIP 1 (antibiotic given within 1 hour of surgery) was associated with rates of surgical site infection among colorectal surgery patients.²⁴ Another study found that none of the individual SCIP INF measures were associated with rates of surgical site infection but that a global composite measure was.²⁵ The other studies found no relation between SCIP INF measures and clinical outcomes.²⁶

Taken as a whole, these studies provide scant evidence for the effectiveness of process compliance in improving outcomes in surgery. Given that the SCIP measures were chosen on the basis of randomized trials supporting their effectiveness, these findings are somewhat counterintuitive. One explanation may be that in the randomized trials, these interventions were assessed under tightly controlled conditions (e.g., patient populations, hospital environments) that

simply are not representative of their use in general practice. This is sometimes referred to as the difference between the effectiveness and the efficacy of an intervention. Another plausible explanation is that high rates of compliance or improvements in rates of compliance are really indicative of better documentation rather than actual compliance or clinical care processes. The three single-site studies^{27–29} showing the effectiveness of these process changes in the prevention of surgical site infections for colorectal surgery patients at their sites following changes in clinical care would support this explanation.

Checklists

Although not yet a target of pay-for-performance or other incentive programs, surgical checklists can be considered another process compliance strategy. Checklists, which have long been used in aviation, came to be used in health care following the publication of a study documenting their effectiveness for the prevention of catheter-related bloodstream infections in intensive care units.³⁰ Surgical checklists range from simple preoperative “timeouts” to prevent rare

but dreadful errors, such as operating on the wrong site or patient, to broad lists of practices known to reduce complications and/or improve teamwork.

Checklists have been the subject of two recent process compliance studies in surgery. A study supported by the World Health Organization (WHO) tested the effects of a 19-item intraoperative checklist among nearly 4,000 patients undergoing noncardiac surgery at eight large hospitals around the world using a pre/post study design.³¹ The second study evaluated the effects of a comprehensive checklist (11-part instrument with more than 100 items, encompassing all phases of care) in six regional and tertiary care centers and five control hospitals in the Netherlands.³² Despite differences in the extensiveness of checklists and in the scientific rigor of the study designs, both studies found that the use of a surgical checklist resulted in dramatic reductions in surgical morbidity and mortality. In the WHO study, mortality was reduced by almost 50% and complications dropped from 11% to 7%. In the de Vries and colleagues study, mortality was also cut in half and rates of complications were reduced from 15% to 11%.³²

In each of the two surgical checklist studies, all types of complications were reduced rather than just those that would be expected based on the content of the checklists. This suggests that checklists may have indirect effects that may be as, if not more important, than their specific content. For example, checklists could reduce the rates of surgical complications by improving hospitals' safety culture, lead to more effective communication and/or handoffs between different types of providers, or reduce distractions in the operating room. The durability of improvements in outcomes attained with checklists is yet to be determined as neither of the two studies had a very long duration of postintervention study time (3 to 6 months). It is also to be determined what specific items are essential for an effective surgical checklist. Nonetheless, checklists should be considered among the more promising interventions for improving rates of morbidity and mortality with surgery.

Outcomes Measurement and Feedback

Many of the professional organizations in surgery have focused their quality improvement efforts on the development and dissemination of clinical registries for tracking surgical outcomes. The goal of these efforts is to provide benchmarking data with which hospitals and surgeons can compare their outcomes with those of their peers. The rationale for benchmarking performance is to allow hospitals to identify opportunities for quality improvement and therefore to be motivated to engage in internal quality improvement activities. The Society of Thoracic Surgeons (STS) is considered a pioneer in this area, and virtually all US hospitals involved in cardiac surgery now participate in its registry. The NSQIP is the largest outcomes measurement platform in noncardiac surgery. The NSQIP was developed for use in Veterans Affairs (VA) hospitals, but since being adapted for use in the private sector by the American College of Surgeons, several hundred private sector hospitals now participate. Finally, a number of states have been measuring and publicly reporting risk-adjusted outcomes

for certain high-risk procedures, most frequently coronary bypass surgery.

There is strong evidence that outcomes measurement and feedback are an effective strategy for reducing rates of surgical morbidity and mortality. For example, surgical complication rates decreased by more than 40% in VA hospitals following the implementation of the NSQIP.³³ Surgical complication rates also dropped among private sector hospitals after the implementation of NSQIP, although much less dramatically than in the VA hospitals.³⁴ Mortality among Medicare patients undergoing coronary bypass surgery in the state of New York declined by 41% between 1989 and 1992 with the implementation of the New York State Department of Health Cardiac Reporting Systems.³⁵ During this same time period, mortality among Medicare patients undergoing coronary bypass nationally declined by only 13%.³⁶ Another study assessed rates of mortality with coronary artery bypass with (Ohio, New Jersey, New York, and Pennsylvania) and without public outcomes reporting systems between 1994 and 1999.³⁷ Coronary bypass mortality rates in states with public reporting systems decreased between 20 and 33% more than those in states without these systems.

Outcomes measurement and feedback can be an effective way to improve surgical care. However, certain conditions are necessary for the success of this approach, including mandatory reporting of all hospitals, audits of data quality, a neutral third party to analyze and report data, and some kind of pressure (e.g., public reporting) for poor performers to improve.³⁸ It also probably works best for procedures where the primary outcomes occur within the perioperative period and can be measured and verified at a relatively low cost. Finally, the way that this approach works is by stimulating improvements among low-performing providers. However, it does not provide those institutions in need of improvement with information they will need to accomplish that goal. Outcomes measurement and feedback programs also do not provide the motivation or the information required to improve care overall.

Regional Collaborative Quality Improvement

Regional collaborative quality improvement goes beyond the measurement and feedback of outcomes data with region-wide implementation of explicit quality improvement interventions. Similar to outcomes measurement and feedback programs, regional collaborative quality improvement programs are based on clinical registry data, which are used to provide regular feedback on performance. Where regional collaborative quality improvement programs differ from straight outcomes measurement and feedback programs is that they convene regularly to review and interpret registry data with a specific focus on areas of variation in practice or outcomes. Once the processes that are associated with the best outcomes (best practices) are identified, they are broadly implemented throughout the region. The Northern New England Cardiovascular Disease Study Group, which started in 1987, is the original regional collaborative quality improvement collaborative. In Michigan, Blue Cross and Blue Shield of Michigan/Blue Care Network (BCBSM/BCN) has funded similar programs in many clinical areas,

including surgery (cardiac, bariatric, and other types of general and vascular surgery).

For many years, the only evidence for the effectiveness of regional collaborative quality improvement has been from the Northern New England Cardiovascular Disease Study Group. During the first 5 years of the collaborative (1987 to 1992), the group received regular feedback on outcomes and training in continuous quality improvement techniques, and teams from each of the hospitals engaged in round robin site visits to observe perioperative care for CABG patients at other sites.³⁹ The CABG mortality rate decreased by 24% over the study time period. A subsequent study based on Medicare data showed that northern New England and New York State had a combination of the lowest CABG mortality rates in 1992 and the greatest improvement in mortality rates over this time period in the country.³⁶

With the funding of numerous regional collaborative quality improvement programs in the state of Michigan, there are now many more data on which to gauge the effects of this approach.⁴⁰ For example, risk-adjusted morbidity rates among patients undergoing general or vascular surgery in hospitals participating in ACS-NSQIP in Michigan fell from 13.1% in 2005 to 10.5% in 2009 ($p < .001$). In contrast, morbidity rates in non-Michigan hospitals participating in ACS-NSQIP remained essentially flat between 2005 and 2008 at approximately 12.5%, before dipping slightly to 11.5% in 2009. Risk-adjusted 30-day mortality with bariatric surgery in Michigan fell from 0.21% in 2007 to 0.02% in 2009 ($p = .004$) [see Figure 2]. During this time period, bariatric surgery mortality at non-Michigan hospitals participating in ACS-NSQIP did not improve significantly (0.18% to 0.11%). In cardiac surgery, during its initial reporting periods (2006 to 2007 and 2007 to 2008), composite quality scores for Michigan hospitals as a whole were statistically indistinguishable from national benchmarks. Michigan hospitals have now achieved a three-star rating from the STS (on an 11-item composite quality measure, which includes risk-adjusted mortality, complications, internal mammary graft use, and several other important processes of care, as

defined by the Adult Cardiac Surgery Registry of the STS), indicating that its aggregate performance exceeded national norms and falls within the top 10th of hospitals nationwide.

Despite growing evidence of the effectiveness of regional, collaborative quality improvement, this approach has not been widely adopted because it is expensive, is complicated to coordinate, and lacks a natural sponsor. The programs in Michigan exist because the state's largest private insurer has not only funded the costs of running them but has also offered additional financial incentives for hospitals to participate. Convincing others, including other private payers, public payers, purchasers, and provider systems, to invest in regional, collaborative quality improvement will require a convincing demonstration of return on investment. Although there are substantial obstacles to more widespread adoption, this is the only approach that works by reducing variation in practice and improving quality overall. In contrast, the other strategies aim to improve performance among poor performers or, in the case of selective referral, to steer patients away from them.

Summary

Each of the approaches to surgical quality improvement addressed in this chapter has advantages and disadvantages. Selective referral strategies are probably best reserved for relatively rare procedures for which outcomes have been shown to vary dramatically according to provider factors such as procedure volume. COE programs that rely on self-reported and unaudited information have not been effective in identifying high-quality providers. As they are currently configured, process compliance programs have mainly focused on improving adherence to a small number of evidence-based practices in perioperative care. That many of the results for process compliance programs have been disappointing may reflect that what these programs have improved is the documentation of clinical care practices rather than the actual clinical care processes. Process compliance efforts involving surgical checklists and the active participation of surgeons and other members of operative teams are having more promising results. Outcomes measurement and feedback programs, especially where they are publicly reported, can motivate local quality improvement efforts among hospitals with poor performance. Finally, regional collaborative quality improvement programs may accelerate improvement by having the ability to rapidly identify and broadly implement best practices. However, this strategy has not been widely adopted, perhaps because of the expense and complexity of these programs as well as their lack of a natural sponsor.

4 EVIDENCE-BASED SURGERY

Samuel R.G. Finlayson, MD, MPH

Evidence-based surgery describes the consistent and judicious use of the best available scientific evidence in making decisions about the care of surgical patients. Evidence-based surgery is part of a broader movement—evidence-based medicine—to apply the scientific method to medical practice. This movement has its historical roots in the pioneering work of the Scottish epidemiologist Archibald Cochrane (1909–1988), for whom the preeminent international organization for research in evidence-based medicine, the Cochrane Collaboration, is named. The term “evidence-based medicine” itself was popularized through a landmark article advocating a new approach to medical education that appeared in the *Journal of the American Medical Association* in 1992.¹ This article urged the de-emphasis of “intuition, unsystematic clinical experience, and pathophysiologic rationale as sufficient grounds for clinical decision making.” In essence, advocates of evidence-based medicine seek to demote “expert opinion” to the least valid basis for clinical decision making. The practice of surgery, once driven more by the eminence of tradition than the evidence of science, now increasingly requires its students to adopt evidence-based scientific standards of practice.

The imperative that surgical care be delivered in accordance with the best available scientific evidence is only one facet of evidence-based surgery. In addition, evidence-based surgery refers to systematic efforts to establish standards of care supported by science, as well as the movement to popularize evidence-based practice. Systematic reviews of the literature are often generated by independent researchers or collaborative study groups (e.g., Cochrane collaborations) and published as review articles in journals or disseminated as practice guidelines. The movement to propagate evidence-based surgical practice is a relatively recent phenomenon exemplified by the collaborative efforts to develop the Surgical Care Improvement Project Core Measure Set² and by the US federal government’s efforts to reward best practices with “pay for performance” policies.³ Although researchers are charged with generating and disseminating scientific evidence, the greatest responsibility for the success of evidence-based surgery is ultimately with individual surgeons, who must not only practice evidence-based surgery but also understand and appropriately interpret an immense surgical literature.

This chapter provides a framework for evaluating the strength of evidence for surgical practices, the validity of scientific studies in surgery, and the role of evidence-based surgery in assessing and improving the quality of surgical care. The intent is to provide the reader with conceptual and

analytic tools that a modern, evidence-based surgeon needs to navigate the surgical literature and implement practices that are based on sound science.

Guidelines and Secondary Sources of Scientific Evidence

To meet the growing demand for evidence-based practice information, a market has developed around the work of pooling and interpreting “best scientific evidence.” Scientific reviews serve as secondary sources for evidence-based practice and are increasingly found in journals, in books, and on the Internet. Prominent examples include *Clinical Evidence* (published semiannually by the *British Journal of Medicine* and continually updated online⁴), the *Cochrane Database of Systematic Reviews*,⁵ and the Institute for Healthcare Improvement.⁶ For surgical practices specifically, the Surgical Care Improvement Project serves as a clearinghouse for evidence-based guidelines.

Efforts to summarize and disseminate information about evidence-based surgery provide a convenient “user interface” for the surgical literature that can be very helpful to practicing surgeons. However, because such aids are far from complete and new evidence emerges continually, surgeons cannot rely on these sources entirely. The modern “evidence-based surgeon” must learn to assess the quality of individual scientific studies and interpret their implications for his or her practice.

Levels of Evidence

Evidence for surgical practice comes in many forms with variable reliability. At one end of the spectrum is an empirical impression that a practice makes physiologic sense and seems to work well. Much of what surgeons do in practice falls into this category and has not been formally tested. At the other end of the spectrum is evidence accumulated from multiple carefully conducted scientific experiments with consistent and reproducible results. The task of the evidence-based surgeon is to judge the reliability of scientific evidence and select practices that conform to the best evidence available.

To help clinicians judge the strength of scientific evidence, researchers have attempted to create hierarchies of evidence, which range from those sources that are most reliable to those that are least sure. With the understanding that not all practices have been subjected to the highest levels of scientific scrutiny, clinicians are advised to base practices on evidence gleaned from studies as high on the evidence hierarchy as possible.

A commonly cited example of such a hierarchy is the “levels of evidence” system popularized by the U.S. Preventive Medicine Task Force (USPMTF) [see Table 1].⁷ Since its inception, the hierarchy of scientific evidence created by the USPMTF has become common parlance among clinicians. Hence, frequently heard references to “level 1 evidence” refer to well-conducted randomized controlled trials. However, almost as soon as the USPMTF released its evidence grading system, debate about its adequacy began.⁸ The predominant criticism has been that the system is too simple and inflexible to accurately describe the strength of evidence for clinical practices. Although the system identifies the design of the study from which the evidence is drawn, it does not describe important factors that influence the quality of the study. For example, in the USPMTF system, the same grade is awarded to a randomized, double-blind, placebo-controlled trial with 50,000 subjects as to an unblinded randomized trial with 30 subjects. The latter trial would, in turn, be graded higher than a well-designed and conducted, multi-institution, prospective cohort study with 10,000 subjects.

In response to these deficiencies, numerous alternative grading systems have been developed that take into account factors other than study design, such as quality, consistency, and completeness. However, it is widely recognized that no single grading system is perfect,⁹ and surgeons are often required to judge the quality and applicability of scientific evidence for themselves.

Appraising Scientific Evidence

Specific study designs are associated with different levels of confidence about cause and effect. The clinical study design that is considered to have the greatest potential for determining causation is the randomized, controlled clinical trial.

Table 1 Levels of Evidence, as Stratified by the U.S. Preventive Services Task Force	
Level of Evidence	Source of Evidence
I	At least one properly randomized controlled trial
II – 1	Well-designed controlled trials without randomization
II – 2	Well-designed cohort or case-control analytic study, preferably from more than one center or research group
II – 3	Multiple time-series with or without intervention or possibly dramatic results from uncontrolled trials (e.g., penicillin treatment in the 1940s)
III	Opinions from respected authorities based on clinical experience, descriptive studies and case reports, or committees of experts
Category of Recommendation	Basis of Recommendation
Level A	Good and consistent scientific evidence
Level B	Limited or inconsistent scientific evidence
Level C	Consensus and/or expert opinion

This simple categorization scheme is generally considered inadequate but is still frequently referenced.

However, even studies with this design can lead to erroneous conclusions if they are not performed properly. Evaluating the quality of clinical evidence requires a close look at how the study that produced it was conceived, implemented, analyzed, and interpreted.

Scientific evidence from studies of clinical practice relies on two important inferences. The first inference is that the observed outcome is the result of the practice and cannot be attributed to some alternative explanation. When this inference is deemed true, the study is considered to have *internal validity*. The second inference is that what was observed in the clinical study is relevant to scenarios outside the study where the surgeon seeks to implement the practice. The extent to which this is true is called *external validity* or *generalizability*. Whereas internal validity relies on how well the study is conducted and the results analyzed, external validity relies on how well the study plan reflects the real-world clinical question that inspired it and how well the study’s conclusions apply to real-world scenarios outside the study [see Figure 1]. Poor external validity can also refer to the difference between an intervention’s efficacy (how well it works when applied perfectly) and its effectiveness (whether it has the same effect when applied generally in an uncontrolled environment).

Evaluating the Quality of a Study: Internal Validity

Assessment of the internal validity of a study requires an understanding of the potential influence of *chance*, *bias*, and *confounding* [see Table 2]. Chance refers to unpredictable randomness of events that might mislead researchers. Bias refers to systematic errors in how study subjects were selected or assessed. Confounding refers to differences in the comparison groups (other than the intended exposure) that lead to differences in outcomes.

CHANCE

In clinical studies that compare outcomes between two or more groups, the assumption that there is no difference in outcomes is called the *null hypothesis*. Erroneous conclusions with regard to the null hypothesis can sometimes occur by chance alone. There are two types of chance-related errors: type I and type II. Type I error (also called *error*) occurs when researchers erroneously reject the null hypothesis, that is, infer that there is a difference in outcomes when there is really no difference. Type II error (also called *error*) occurs when researchers erroneously confirm the null hypothesis, that is, infer that there is no difference in outcomes when, in reality, a difference exists.

Type I Errors

Statistical testing is used to quantify the likelihood of a type I error. A “*p* value” indicates the probability that observed differences between groups might be due to chance alone. The threshold for “statistical significance” is conventionally set at a *p* value of .05, signifying that the likelihood of the observed differences being due to chance alone is 5 out of 100. Although a likelihood of 5% falls short of absolute certainty, this level of confidence is generally accepted as scientific proof.

An alternative expression of statistical likelihood is confidence intervals. Confidence intervals show the range of

Figure 1 Processes that affect the internal and external validity of a clinical study.

Table 2 Methods Observed in Published Clinical Studies that Demonstrate Efforts to Minimize the Effects of Chance, Bias, and Confounding

Chance

Power calculations during design of the study
Appropriate statistical test to avoid type I error
Large enough sample size to avoid type II error

Bias

Prospective study designs
Careful subject selection
 Good sampling strategy
 Appropriate inclusion and exclusion criteria
Blinding
Clear and careful protocols for data collection

Confounding

Study design
 Randomization
 Restriction
 Matching
 Instrumental variables
Data analysis
 Risk adjustment
 Stratification
 Propensity scores

the observed difference that would be expected if the same study were repeated an infinite number of times. For example, a 95% confidence interval would include the observed difference 95% of the times that the study was repeated.

Many statistical tests can be used to calculate *p* values and confidence intervals. The appropriate statistical test must be selected according to several factors, including the number of observations in the comparison groups, the number of groups being compared, whether two or more groups are being compared with each other or one group is being compared with itself after some interval of time, what kind of numerical data are being analyzed (e.g. continuous, categorical), or whether risk adjustment is required. Although most surgeons are unlikely to fully comprehend all of the nuances of more complex statistical analyses, most clinical surgical studies are designed simply enough to employ statistical tests that are within reach of the nonstatistician. Fortunately, several useful and concise texts are available that can help surgeons become conversant in basic statistical methods.^{10–12}

Type II Errors

Type II errors (erroneously accepting the null hypothesis) often occur when sample size is simply insufficient to detect small but clinically important differences in outcomes. When a study's sample size is too small to detect differences in outcomes between comparison groups, it is said to lack sufficient statistical power. Once a study is complete, no amount of analysis can correct for insufficient statistical power. Before starting a study, researchers should perform a "power calculation," which involves determining the minimum size of a

meaningful difference in outcomes and then calculating the number of observations required to show that difference statistically. Surgeons should be particularly cautious when evaluating studies with null findings, particularly when no power calculation is explicitly reported. An evidence-based surgeon is wise to remember the adage, “No evidence for effect is not necessarily evidence of no effect.”

BIAS

Bias refers to a systematic problem with a clinical study that results in an inaccurate estimate of the differences in outcomes between comparison groups. There are two general types of bias: *selection bias* and *measurement bias*. The former results from errors in the choice of study subjects. The latter results from errors in the way information about exposures or outcomes (or other pertinent data) is obtained.

Selection bias refers to any imperfection in the selection process that results in either the wrong types of subjects (people who are not typical of the target population) or a sample of subjects that is for some reason (unrelated to the intervention) more likely to have the outcome of interest. For example, paid volunteer subjects may be more motivated to comply with treatment regimens and report favorable results, resulting in an overestimate of the effect of an intervention. This would affect both internal validity (inference about size of the effect) and external validity (generalizability to other populations). As another example, selecting subjects from among diners at a Szechuan Chinese restaurant for a trial of medical versus surgical treatment of gastroesophageal reflux might lead to results favoring medical treatment (people with reflux who consume Szechuan Chinese food are more likely to have symptoms that are already well-controlled medically). When assessing the validity of scientific evidence, surgeons must carefully consider the characteristics of the subjects selected for study.

Measurement bias refers to problems caused by the way information about outcomes or other pertinent data is obtained. For example, in a study of sexual function after surgery for rectal cancer, subjects may report symptoms differently in an in-person interview than they would in an anonymous mailed survey. As another example, using surgeons to assess hernia repair outcomes in their own patients might result in erroneous reported rates of chronic pain. Retrospective studies are particularly prone to a variety of types of measurement bias. For example “recall bias” may occur because of subjects’ selective memory of past events, and “ascertainment bias” may occur if the outcome is likely to influence how hard observers look for information about exposures. Sources of measurement bias may be more subtle than selection bias and require careful attention to reported study methods. Efforts to control measurement bias include blinding (not telling the subject or assessor what intervention was performed) and prospective study design.

Confounding

Confounding refers to differences in outcomes that occur because of differences in the baseline risks of the comparison groups. Confounding is often the result of selection bias. For example, a comparison of mortality after open versus laparoscopic colectomy might be skewed because of the greater likelihood of open colectomy being performed as an emergency in a critically ill patient. In this example, the severity of the

illness confounds the observed association between mortality and surgical approach.

In evaluating the strength of evidence in a published study, readers must assess how well the researchers accounted for the potential effect of confounding. Confounding can be minimized in several ways, both in the design of the study and in the analysis of the study’s results. In the design of a study, confounding is most effectively addressed with *randomization*. When subjects are randomized, potentially confounding variables (both recognized and unrecognized) are likely to be evenly distributed across comparison groups. Thus, whereas the baseline rate of outcomes in the entire cohort might be influenced by these factors, the differences across comparison groups are less likely to be affected.

Where randomization is not practical, *restriction* or *matching* can be used to prevent confounding. Restriction refers to the tight control of study entry criteria (e.g., enter only elective colectomy cases in the study described above). However, restrictive entry criteria can sometimes limit generalizability. Matching refers to using a comparison group of unexposed (control) subjects who are identical to the exposed (case) subjects across a set of characteristics (e.g., age, sex, residence) that have the potential to result in confounding.

A more complicated technique used to limit the effect of confounding is *instrumental variable analysis*. This approach involves studying the effect of a given exposure on outcomes by comparing groups with different levels of a third factor (the instrumental variable) that is highly correlated with the exposure but does not independently affect the outcome.¹³ For example, an observational study of the effect of catheterization and revascularization on mortality following acute myocardial infarction is prone to confounding related to differences in baseline health characteristics of the populations receiving or not receiving these treatments. To limit this potential source of confounding, a group of researchers studied the effect of these treatments (the exposure) on mortality after myocardial infarction (the outcome) by comparing groups of patients living at different distances from hospitals providing these services (the instrumental variable).¹⁴ The researchers assumed that potentially confounding health characteristics would be distributed randomly geographically and that geographic distance would affect mortality only indirectly through its correlation with access to treatment. In a way, they used distance to “randomize” their study population to different levels of treatment for acute myocardial infarction.

In addition to minimizing confounding through good study design, confounding can also be addressed during the analytic phase of a study. The most common approach is the use of *statistical risk adjustment* techniques, typically with multivariate regression analysis. This approach involves taking into account differences in the prevalence of recognized confounders across comparison groups. However, statistical risk adjustment has two important limitations. First, only recognized confounders can be addressed. Second, every potential confounding variable added to a statistical model decreases the model’s statistical power and thereby increases the chance of resulting in a type II error.

Other analytic techniques used to address confounding include *stratification* (subanalyses in which subjects with similar risk profiles are compared) and *propensity score risk*

adjustment.¹⁵ The latter technique addresses the problem created by unequal chances of receiving treatment caused by differences in health characteristics. In an observational study of the outcomes of a given treatment, a propensity score is a scalar summary of all observed confounders that predict the probability of receiving the treatment. Propensity scores are typically calculated using multivariate regression models and are used as the basis for stratified analysis or for matching cases and controls in observational studies.

Interpreting and Applying Evidence to Practice: External Validity

Once one is convinced that a clinical study is internally valid (i.e., that the observed outcome is the result of the exposure or intervention and cannot be attributed to some alternative explanation), then the challenge to the surgeon is judging the study's external validity (i.e., determining whether the findings are applicable to the clinical scenario he or she faces). An assessment of external validity requires attention to several components of a clinical study, including the patient population, the intervention, and the outcome measure. In the discussion that follows, a large prospective randomized clinical trial of laparoscopic versus open inguinal hernia repair performed in the Veterans Administration (VA) will be used as an illustrative example.¹⁶ This trial concluded that outcomes of open repair are superior to those of laparoscopic repair. The trial was well designed and well conducted but generated substantial discussion about the generalizability of the results.

As noted above, subject selection bias can adversely affect the external validity (or generalizability) of a study's results. If the population studied is in some important measure different from the population for which a surgeon is making clinical decisions, he or she may not achieve similar results. In the VA hernia trial, subjects were military veterans, who tend to be, on average, older than the nonveteran general population. If older subjects are more prone to the risks of laparoscopic hernia repair (e.g., general anesthesia), one might expect that the difference in morbidity outcomes would be exaggerated in the VA trial. In this respect, a surgeon might consider the evidence provided by the trial applicable to his or her older patients but reserve judgment on the use of laparoscopy to repair hernias in younger, healthier patients.

A striking example of the potential effect of selection bias on generalizability comes from the Asymptomatic Carotid Artery Stenosis (ACAS) trial.¹⁷ In this large prospective randomized study, volunteers for the trial were substantially younger and healthier than the average patient who undergoes carotid endarterectomy. As a result, the observed perioperative mortality rate in the trial was considerably lower than that observed in the general population or even in the very hospitals where the trial was conducted.¹⁸ Although the results of the ACAS trial significantly changed practice, one could argue that the evidence provided by the ACAS trial may have been generalizable only to younger populations.

The external validity of a clinical study can also be affected by who provides the intervention and by what type of intervention is provided. In the VA hernia trial, surgeons had variable experience with the laparoscopic approach, and the trial reported twofold differences in hernia recurrences between

surgeons who had done more than 250 cases and surgeons who had less experience. Surgeons deciding whether evidence supports the use of laparoscopic repair would need to examine their own experience before determining the generalizability of this study to their practices. Furthermore, some have argued that one of the laparoscopic techniques commonly used in the VA trial (transabdominal preperitoneal repair) is outmoded and more hazardous.¹⁹ Surgeons who avoid using this approach might reasonably question the generalizability of this study to their practices.

The type of outcome measured can also affect the generalizability of clinical studies. Outcomes chosen for clinical studies may be those that are most convenient or most easily quantified and may not be the outcomes of greatest interest to patients. In the VA hernia trial, several outcomes were studied, including operative complications, hernia recurrence, pain, and length of convalescence. Some of the outcome differences favored open repair, whereas some favored laparoscopic repair. The interpretation of the trial evidence for one type of repair versus the other involves implicit value judgments regarding which outcomes are most important to patients. Surgeons applying the VA hernia trial evidence to decisions about hernia repair must examine the specific outcomes measured before knowing whether a study is generalizable to an individual patient with specific values and interests.

Evidence-Based Surgery and Quality of Care

In clinical studies, the efficacy of a surgical practice is measured in terms of the resulting patient outcomes. Similarly, efforts to assess the quality of surgical care have until recently focused almost exclusively on clinical outcomes. In recent years, however, the movement to promote evidence-based surgery has offered an alternative measure of surgical quality: adherence to processes of care (e.g., routine use of perioperative antibiotics) supported by the best available scientific evidence.

The question of whether efforts to assess quality should focus on evidence-based processes of care or clinical outcomes is as much practical as philosophical. The practical argument against outcomes is largely driven by a growing recognition that individual hospitals and surgeons generally have too few adverse outcomes to provide enough statistical power to show meaningful differences between providers.²⁰ The practical argument against evidence-based processes of care is driven by the paucity of high-leverage, procedure-specific processes for which sound evidence is available, as well as the logistical challenge of measuring such processes. A more complete discussion of this topic is provided elsewhere [see *EC:2 Performance Measures in Surgical Practice*].

Given its current momentum, the evidence-based surgery movement will likely play a progressively larger role in efforts to assess and improve quality of surgical care. Furthermore, as payers increasingly turn to "pay for performance" strategies to improve quality and control costs, the demand for evidence-based practice guidelines will continue to grow. More importantly, efforts to identify and implement evidence-based surgical practices will ultimately provide patients with safer, better care.

5 PATIENT SAFETY IN SURGICAL CARE: A SYSTEMS APPROACH

Robert S. Rhodes, MD, FACS, and Caprice C. Greenberg, MD, MPH, FACS

High-profile catastrophes such as the explosion of the nuclear power plant at Chernobyl, the near meltdown of the nuclear power plant at Three Mile Island, the explosion of a chemical plant in Bhopal, numerous aviation disasters, and the loss of the space shuttles *Challenger* and *Columbia* share important characteristics. First, the casualties are notable for their number, their celebrity, or both. Second (and more germane to this chapter), each occurred as a result of multiple failures within complex systems. Human errors played a role in all of these failures, but the errors were not single acts of negligence as much as they were magnifications of multiple seemingly small interactions, the significance of which was initially unrecognized or underestimated.

Until about a decade ago, medical errors, unlike the above events, rarely received much publicity. This was in part because they affected only one patient at a time, and, as a result, their aggregate number was neither recognized nor well publicized. Another factor has been the tendency to regard error in medicine as a special case of medicine rather than as a special case of error.¹ The unfortunate result of this view has been the isolation of medical errors from much of the body of theory, analysis, and application that has been developed to deal with error in other high-risk work domains such as aviation and nuclear power.

Yet at least two factors now appear to be changing this view. One, the 1999 report of the Institute of Medicine (IOM), *To Err Is Human: Building a Safer Health System*, made national headlines with its estimates of the frequency and severity of adverse events in health care, including that as many as 98,000 medical error-related deaths occur each year in the United States.² This estimate far exceeds the number of casualties from more publicized nonmedical disasters, and if it is accurate, then medical errors would be one of the leading causes of death in the United States. Moreover, surgical adverse events represent over half of all adverse events experienced by hospitalized patients, and 75% of those have their origin in the operating room.³ This highlights the critical importance of patient safety in surgical care, particularly in the operating room.

A second factor affecting this view was advances in cognitive psychology that greatly increased the understanding of the influences that lead to error and affect human performance. The observation that the basic principles of human error are highly applicable to clinical practice has markedly advanced our understanding and willingness to address error in this setting. Medical errors are not a special case of medicine, and their underlying causes are not unique to medical practice.

These factors also challenged the notion that medical injury is primarily the result of “bad apples” and that safety can be improved largely by ridding the system of these persons. Undoubtedly, bad apples exist, but it is increasingly clear that health care-related injuries represent system failures and are rarely solely the result of negligence on the part of a single provider. Furthermore, there is a growing recognition that modern health care systems are as complex as—if not more complex than—the systems associated with nuclear power, aviation, and space flight.¹ The cognitive and technical complexity of the tasks performed in the operating room, the intensive care unit, and the emergency department certainly rivals that of these other endeavors. Furthermore, optimal patient care increasingly requires coordination among an expanding number of participants. For instance, in the early 20th century, it is estimated that health care involved the interaction of three persons, on average; a century later that number had risen to 16.

This chapter seeks to address the characteristics of systems in general and the system of surgical care in particular. It describes the growing knowledge of factors that affect human performance and how these factors contribute to adverse surgical outcomes. The chapter also outlines current obstacles to improving safety, identifies systems approaches to making improvements, and discusses ways in which surgeons can take the lead in overcoming these obstacles. An overall goal is that acceptance of error and a willingness to investigate its underlying causes will allow health care professionals to make use of the lessons learned from study of nonmedical systems. Although issues of patient safety are often intertwined with those of the overall cost-effectiveness and quality of surgical care,⁴ the latter are discussed in greater detail elsewhere.

Nature and Magnitude of Adverse Events in Surgical Care

For most of the important concepts bearing on patient safety in the surgical setting, generally accepted definitions exist [see *Sidebar Definitions of Terms Related to Patient Safety*]; the ensuing discussion is based on these definitions.⁵ A solid understanding of the key concepts—such as the distinctions between an adverse event (or adverse outcome), an error, and negligence—is critical for managing errors as system failures rather than as isolated incidents.⁶ In particular, such an understanding can help in navigating the often turbulent emotional milieu that can surround adverse patient events. Given their motivation to help patients, physicians tend to be highly sensitive to issues of causation, and this

Definitions of Terms Related to Patient Safety⁵

- An *adverse event* is an injury that was caused by medical management and that results in measurable disability.
- An *error* is the failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim. Errors can include problems in practice, products, procedures, and systems.
- A *preventable adverse event* is an adverse event that is attributable to error.
- An *unpreventable adverse event* is an adverse event resulting from a complication that cannot be prevented given the current state of knowledge.
- A *near miss* is an event or situation that could have resulted in accident, injury, or illness but did not, either by chance or through timely intervention.
- A *medical error* is an adverse event or near miss that is preventable with the current state of medical knowledge.
- A *latent error* is a condition of the system that is removed from the adverse event, such as poorly designed equipment, management decisions, or physical plan of the operating room. Latent errors set up the conditions in which an adverse event can occur, but their impact is not directly recognized.
- An *active error* is an action that directly leads to the adverse event.
- A *system* is a regularly interacting or interdependent group of items forming a unified whole.
- A *systems error* is an error that is not the result of an individual's actions but the predictable outcome of a series of actions and factors that make up a diagnostic or treatment process.

sensitivity can then interfere with the recognition and management of safety issues.

The two most widely cited estimates of adverse medical events derive from the Harvard Medical Practice Study (HMPS)⁷ and from a study in Colorado and Utah.³ The HMPS, a population-based study of patients hospitalized in New York State during 1984, found that nearly 4% of patients experienced an adverse event and that about half of such events occurred in surgical patients. The Colorado/Utah study, which randomly sampled 15,000 nonpsychiatric discharges during 1992, found that the annual incidence of adverse surgical events was 3.0% and that 54% of these events were preventable. Nearly half of all adverse surgical events were accounted for by technique-related complications, wound infections, and postoperative bleeding. This study also identified common operations that were associated with a significantly higher risk of an adverse event and a significantly higher risk of a preventable event.

Other studies yielded comparable or higher estimates,⁸ and still others evaluated the rates at which specific events occurred, as follows:

- Retained sponges or surgical instruments were estimated to occur at a rate between one in 8,801 and one in 18,760 inpatient procedures at nonspecialty acute care hospitals.⁹
- Wrong-site surgery is more than just an isolated event,¹⁰ and the apparent increased frequency at which such events are currently being reported probably reflects previous underreporting.
- Medication errors (e.g., wrong drug, wrong dose, wrong patient, wrong time, or wrong administration route) are alarmingly frequent.^{11,12} The US Pharmacopeia monitors these events through its reporting programs (www.usp.org/

patientsafety). In 2001, these programs received reports of 105,603 errors, 2,539 (2.4%) of which resulted in patient injury. Of these, 353 necessitated hospitalization or prolonged its duration, 70 necessitated interventions to sustain life, and 14 resulted in a patient's death. The main contributing factors were distractions (47%), workload increases (24%), and staffing issues (36%). Miscalculating patient weight conversions (e.g., from pounds to kilograms) and subsequent improper dosing are all too common among pediatric patients. Errors in the administration of radiopharmaceuticals are also frequent and may involve the wrong isotope (68.9%), the wrong patient (24%), the wrong dose (6.5%), or the wrong route (0.6%).¹² One study estimated that the US rates would have to be reduced by one third to match the benchmark rates in Germany and the United Kingdom with regard to medical mistakes, medication errors, or laboratory test errors.¹³

- Blood transfusions continue to be plagued by patient misidentification.
- Device-related deaths and serious injuries also occur at an alarming rate, even after premarket safety testing.¹⁴ The Food and Drug Administration (FDA) maintains a registry of the thousands of such injuries that occur each year.
- A survey noted that 35% of physicians and 42% of the public said that they had experienced a medical mistake in their own care or in the care of a family member.¹⁵

As might be expected, the IOM report prompted a great deal of debate. Some medical professionals questioned the accuracy of the estimates, whereas others disagreed with the definitions of medical error and adverse event, with the extent to which either or both were considered preventable. Still others argued that adverse events that are caused by conceptual errors (e.g., a contraindicated, unsound, or inappropriate approach) should be differentiated from the side effects of an intended action that is correct in the circumstances (e.g., an indicated diagnostic or therapeutic procedure).¹⁶ The aim of this argument was to sharpen the distinction between accidents (i.e., unplanned, unexpected, and undesired events) and true side effects (which result from correct management and which are often accepted as reasonable therapeutic tradeoffs).

The HMPS attempted to address these issues by characterizing adverse events as either preventable or unpreventable in the light of the prevailing state of knowledge. Preventable errors were further subclassified as either diagnostic errors or treatment errors; treatment errors included preventive errors such as failure of prophylaxis and failure to monitor and follow treatment.^{7,17} The HMPS found that preventability varied according to the type of event: 74% of early surgical adverse events were judged preventable, compared with 65% of nonsurgical adverse events, and more than 90% of late surgical failures, diagnostic mishaps, and nonprocedural therapeutic mishaps were judged preventable.

The above estimates of patient injury rates have also raised speculations about trends in the frequency of these events. To some, the observation that the rate of such events was lower in the Colorado/Utah study than in the HMPS suggests

that patient safety was improving even before the IOM report. Although there may be some improvements in care, wide gaps in quality persist (www.healthgrades.com/business/study/quality.aspx).

Regardless of any actual trend, there is agreement that progress since the IOM report has been slow, that the results have been modest at best, and that the gap between the best possible care and the care actually being delivered remains large.^{18–20} Although the lack of more evident improvement has been somewhat disappointing, clear progress has nevertheless been made with respect to (1) understanding the complexities of medical care systems, (2) identifying the challenges to improving these systems, and (3) developing new perspectives on the assessment of errors. Thus, an increase in estimates of the incidence of adverse events may simply reflect improved reporting rather than actual increases in their occurrence.

Nature and Characteristics of Systems

A system may be broadly defined as a regularly interacting or interdependent group of items that form a unified whole. System functions or tasks usually involve sequential steps that have human, technological, and logistical components. The overall probability of a system failure (i.e., an adverse outcome), then, is a function of the probability of error within each step, the total number of steps, and the degree to which the steps are coupled. The degree of coupling is the extent to which an error at one step can propagate through subsequent steps and adversely affect the final outcome. Loosely coupled systems tend to have built-in redundancy that acts as a safety barrier to prevent errors from propagating to subsequent steps. As a result, satisfactory outcomes in such systems are far less dependent on successful completion of each step. Errors in loosely coupled systems are more readily “trapped” by these safety barriers.

In contrast to loosely coupled systems, tightly coupled systems have relatively little redundancy and relatively few fail-safe mechanisms. Consequently, successful outcomes in tightly coupled systems are highly dependent on the success of each step in essentially a factorial fashion. Thus, the probability of success in a tightly coupled linear 20-step process with a 1% likelihood of error at each step is equivalent to 0.99 factored 20 times, or 0.818. Thus, even though the probability of error for each step is .01, the overall likelihood of an unintended outcome is 0.182.

Given that safety barriers are generally more numerous in loosely coupled than in tightly coupled systems, it is relatively unusual for an isolated error to produce an injury or system failure in the former. Thus, failures in loosely coupled systems typically involve malfunctions at multiple steps. A tradeoff with the level of redundancy in loosely coupled systems is that it makes the system more complex, and the added complexity can introduce its own errors.

James Reason was the first to distinguish between active and latent system errors and their individual importance in understanding the overall role in system failures.²¹ Active errors are what might be traditionally associated with the term “error”: a discrete action that produces an immediate effect. Latent errors, on the other hand, are structural characteristics of the system, features of the environment, or

decisions or plans that are removed from the point of care. They do not produce an immediate result but rather set up the conditions in which a given result can arise. The importance of a system’s latent failures as contributing factors in adverse outcomes may be illustrated by considering a general schema of an injury [see *Figure 1*].²¹ Whereas overt system problems are relatively easy to identify and correct, latent failures are insidious and often do not become evident until a seemingly improbable series of events produces errors in otherwise routine processes. Latent failures tend to be introduced by persons who work at the “blunt end” of the system (e.g., management or housekeeping) but do not actively participate in the main processes of care. A typical injury pathway is one in which organizational processes introduce latent failures, which in turn produce system defects, which in turn interact with external events so that persons who work at the “sharp end” of the system (e.g., anesthesiologists, nurses, or surgeons) commit unsafe acts. These unsafe acts precipitate an active failure that then penetrates the final safety barrier or barriers.²² Indeed, the greatest risk of an adverse event in a complex system may come not from a breakdown of one or more major subsystems or from isolated operator errors but from the presence or accumulation of latent failures.^{21,23,24}

Surgical Care as a System

The characteristics of systems already discussed (see above) have many attributes directly applicable to medicine in general and to surgery and anesthesiology in particular. In addition to the parallels between the habitats associated with surgery (e.g., the operating room, the intensive care unit, and the emergency department) and those associated with many high-tech, high-risk nonmedical endeavors, strong parallels exist between observed behavior in the operating room and behavioral issues in an airplane cockpit.^{25,26}

The nature of the operating room as a system and the complexity of the interactions that occur there have been studied extensively. The performance of the operating room system depends on the individual performance of practitioners, the interactions of those individuals or teamwork, and the environment in which the practitioners work. It is important to note the interdependence of each of these components of the system. To understand the role that each plays, we examine each and their impact on surgical safety in turn: individual performance, teamwork, and environmental or structural factors.

Factors that Affect Performance

COGNITIVE PSYCHOLOGY OF INDIVIDUAL PERFORMANCE

Because human factors play a major role in system failure, any attempt to improve patient safety must be based on an understanding of the factors that affect human performance and their relation to human error.²⁷ Major advances in the field of cognitive psychology over the past several decades have greatly enhanced the understanding of human performance. A widely accepted schema classifies such performance into the following three types,²⁸ in descending order of familiarity with the specific task:

Figure 1 Schematic depiction of the process by which system failures (latent and active) may lead to injury. Defenses may be inadequate if they allow the formation of a window of injury opportunity.

1. *Skill-based performance.* This type of performance is governed by stored patterns of preprogrammed instructions. It occurs without conscious control and uses long-term memory.
2. *Rule-based performance.* This type involves solving problems by means of stored rules of the if-then variety. Like skill-based performance, it uses long-term memory; however, unlike skill-based performance, it is associated with a consciousness that a problem exists.²³ The rules are usually based on experience garnered from previous similar situations and are structured hierarchically, with the main rules on top; their strength appears to be a function of how recently and how frequently they are used.²⁷ Rule-based performance varies according to expertise: novices tend to rely on a few main rules, whereas experts have many side rules and exceptions.
3. *Knowledge-based performance.* This type involves conscious analytic processes and stored knowledge. It relies on working memory, which is comparatively slow and of relatively limited capacity. Typically, people resort to knowledge-based performance when their existing skills are not applicable or their repertoire of rules has been exhausted.

Successful performance or problem solving has three main phases: planning, storage, and execution. Errors resulting from failures in performance may be classified as slips, lapses, or mistakes,²¹ depending on which phase of the problem-solving sequence is involved. Slips are failures of the execution phase, the storage phase, or both, and they may occur regardless of whether the plan from which they arose was adequate. Lapses are failures of the storage phase. Generally, slips are overt, whereas lapses are covert. Mistakes are failures of planning, reflecting basic deficiencies or failures in selecting an objective or specifying the means to achieve it, regardless of how well the plan was executed.

A key concept is that specific types of error tend to be associated with specific modes of failure [see Table 1].²¹ Slips and lapses are failures of skill-based performance and generally precede recognition of a problem. Mistakes may be either

Table 1 Common Modes of Failure Associated with Specific Types of Performance²¹

Failures of Skill-Based Performance

Inattention

- Double-capture slips
- Omissions following interruptions
- Reduced intentionality
- Perceptual confusions
- Interference errors

Overattention

- Omissions
- Repetitions
- Reversals

Failures of Rule-Based Performance

Misapplication of good rules

- First exceptions
- Countersigns and nonsigns
- Informational overload
- Rule strength
- General rules
- Redundancy
- Rigidity

Application of bad rules

- Encoding deficiencies
- Action deficiencies
- Wrong rules
- Inelegant rules
- Inadvisable rules

Failures of Knowledge-Based Performance

Selectivity

- Workspace limitations
- Out of sight, out of mind
- Confirmation bias
- Overconfidence
- Biased reviewing
- Illusory correlation
- Halo effects
- Problems with causality
- Problems with complexity

failures of knowledge-based performance (i.e., attributable to lack of expertise) or failures of rule-based performance (i.e., attributable to failure of expertise). They typically arise during attempts to solve a problem. Mistakes tend to be more subtle,

more complex, and less well understood than slips or lapses and thus more dangerous. It has been suggested that experienced surgeons are more prone to slips and lapses and that junior surgeons and trainees are more prone to mistakes.²⁹

Underspecification of the problem is common in clinical practice and clearly affects performance. A problem may seem underspecified when limited attention is paid, when the wrong cues are picked up, when the problem is truly ill-defined, or when the problem falls outside the known rules. Underspecification is more likely to occur in situations where cues change dynamically or are ambiguous and is associated with two types of error forms: similarity matching and frequency bias (or frequency gambling). In similarity matching, a present situation is thought to resemble a previous one and consequently is addressed in the same way (which is not necessarily appropriate). In frequency gambling, a course of action is chosen that has worked before, and the more often that course of action has been successfully used, the more likely it is to be chosen. These behavior patterns have been confirmed among anesthesiologists, who, like many dynamic decision makers, use approximation strategies (or heuristics) to handle ambiguous situations.¹

Confirmation bias is another characteristic problem of performance. It may be defined as the propensity to stick with a chosen diagnosis or course of action and either to interpret new information so as to favor the original choice or to disregard such information entirely. It is also referred to as cognitive fixation, cognitive lockup, or fixation error and is often associated with knowledge-based performance.³⁰ Confirmation bias is particularly likely when the situation is unusual or evolving and when there is concomitant pressure to maintain coherence³¹—again, situations frequently encountered in surgical practice. A well-known adage is relevant here: good surgeons believe what they see; bad ones see what they believe.³² The issue of how cognitive psychology affects diagnostic and clinical reasoning has been addressed in detail elsewhere.^{33–35}

Confirmation bias may be considered an error of perception; other errors may be classified as errors of cognition or execution. Thus, classification schemes may be modified to meet specific needs.³⁶ For instance, some experts categorize errors according to whether they can be addressed by engineering, design, societal, or procedural changes; others prefer to emphasize psychological intervention and modification; and still others classify errors by their mode of appearance—for example, as errors of omission, errors of insertion, errors of repetition, or errors of substitution (e.g., misadministration of lidocaine, heparin, or potassium chloride as a result of poor package labeling).

RELATION OF INDIVIDUAL PERFORMANCE TO SURGICAL ERROR

To many, the concepts of performance and error, as they relate to patient care, seem straightforward—obvious, even. To others, however, it is crucial to make a distinction between human error and human performance, both because the assignment of error is often retrospective and thus subject to hindsight bias and because the term “error” is inherently prejudicial.

Important advances in our understanding of the role of surgeon performance in error come from an analysis of

surgeon-reported errors³⁷ and a review of closed malpractice claims.³⁸ In the former, cognitive factors (primarily involving errors in judgment or vigilance) were involved in 86% of the incidents, whereas inexperience or lack of competence contributed to 53% of errors. The latter study reported similar findings: errors in judgment, failure of vigilance or memory, and lack of technical competence or knowledge were factors in 66%, 63%, and 41% of the cases, respectively.

Further analysis revealed that 65% of the technical errors were linked to manual error, 9% to errors in judgment or knowledge, and 26% to both manual and judgment or knowledge error.³⁹ Seventy-three percent of technical errors occurred with experienced surgeons operating within their field of expertise, and over 80% were performing routine operations but often under extenuating circumstances, such as complicated patient factors (61%) or systems failures (21%). Current approaches to decreasing technical performance include such interventions as volume-based referral or regionalization, increased specialization, and more stringent credentialing for high-risk procedures. The results of this study, however, suggest that these approaches are unlikely to lead to significant improvement. Rather, attention should be paid to improving technical performance (including both manual and judgment) in general but particularly when operating under complicated conditions.

In one sense, a surgeon's performance is a system factor, but in another sense, their cognitive and technical abilities make up a large part of the system's safety barriers. There is much that can be learned about human performance by studying how providers compensate when things start to go wrong and return the system to a safe state. Legal concerns aside, it is vital that surgeons not overemphasize the first sense and interpret it as an excuse for avoiding responsibility for complications.⁴⁰ Nevertheless, placing too much emphasis on surgeons' individual role retards rather than advances understanding of system failure and tends to evoke defensiveness rather than constructive action.^{22,23,41} Regardless of whether these adverse events are performance failures or errors, eliminating them entirely is an impossible goal; a more realistic goal is to gain a better understanding of the contributing and compensatory factors and then to minimize—or possibly even eliminate—their consequences. The overall implication here is that to achieve meaningful improvements in safety, it is necessary to shift the focus from fallible individuals to the situational and organizational circumstances through which human performance leads to medical errors.²⁶

Another important consideration in performance is an individual's physical and psychological well-being. The effects of sleep deprivation and fatigue on performance and learning have been particularly studied.^{42–46} Fatigue, by impairing vigilance, can accentuate confirmation bias. In addition, errors increase as time on task increases; no other hazardous industry permits—let alone requires—employees to work the regular long hours common in hospitals.³⁰ Stress may increase the likelihood of error, but it is clearly neither necessary nor sufficient for cognitive failure.²¹ Unfortunately, physicians tend to have unrealistic beliefs about their ability to deal with stress and fatigue and so may not seek help even when they clearly need it.⁴⁷ Recent studies have highlighted the striking prevalence of burnout among surgeons and the high degree

of correlation between burnout and medical errors.⁴⁸ Surgeons also appear to have only a limited ability to assess their own learning needs, with those who are least skilled and those who are most confident being the worst at this task.⁴⁹ As a corollary, surgical skill is positively related to the ability to detect errors.²⁹

The mental overload that can occur in situations involving a plethora of tasks may compromise the ability to respond to secondary tasks. Errors related to loss of vigilance include not observing a data stream at all, not observing a data stream sufficiently frequently, and not observing the particular data stream that is optimal for the existing situation. In watching for rare occurrences (a not uncommon situation in medicine), it is difficult to remain fully alert for longer than 10 to 20 minutes. Knowing when and how to verify data is an important metacognitive skill. An analysis of intraoperative safety identified high workloads, poor workload leveling, and multiple competing tasks as a major threat to performance and safety.⁵⁰

In addressing these types of errors, a great deal of emphasis has been placed on reducing work hours, but there seems to have been relatively little consideration of the impact of workload and workflow on medical errors.³⁷ Yet data on resident work activities indicate that residents experience extremely fragmented workflows that result in frequent interruptions and changes in focus.⁵¹ Moreover, the current limit on resident work hours does not appear to have improved patient safety⁵² or reduced the incidence of technical complications.⁵³ Thus, demands for greater productivity within a health care system that is increasingly constrained by cost considerations may also contribute to an increase in medical errors.

Psychological framing effects also play a role in judgment. Examples of such effects are the irrational preference for established treatments when outcomes are framed in terms of gain (e.g., survival) and the similarly irrational preference for risky treatments when outcomes are framed in terms of loss (e.g., mortality). The impetus to “do the right thing” can adversely affect medical judgment.⁵⁴

RELATION OF SYSTEM FACTORS TO SURGICAL ERROR

Teamwork and Communication

Teamwork and communication among team members also play essential roles in determining performance, particularly when there is a lack of cohesion and mutual support among team members.^{1,30} On the one hand, a team structure that is too informal tends to undermine patterns of authority and responsibility and to hinder effective decision making. On the other hand, a hierarchy that is too strong may make it excessively difficult for juniors to question decisions made by those at higher levels of authority. Rigid behavior may impair the ability to cope with unforeseen events and discourage initiative.

Teamwork can be an especially complex matter in the operating room. The crews from nursing, surgery, and anesthesia often have fundamentally different perceptions of their respective roles, and these perceptual differences can adversely affect situational awareness. For example, anesthesiologists and nurse anesthetists are much more likely to feel that a preoperative briefing is important for team effectiveness than are surgeons and surgical nurses. In aviation, concern that

junior team members would not question the decisions of more senior staff led to significant policy changes and safety enhancements.⁵⁵ Given the traditional surgical hierarchy, similar attitudes may exist in the operating room. Such varying perceptions can not only compromise patient safety but also hinder teaching and learning. Unfortunately, there is no broad consensus on how to achieve optimal team coordination in this setting.

The critical role of communication in surgical errors has been described in a number of studies. Two or more clinicians substantially contributed to error in 70% of surgeon-reported errors, and three or more were involved in 18% of the incidents.³⁷ Communication breakdowns contributed to approximately one quarter of surgical errors that led to patient injury as detected on malpractice claims analysis.⁵⁶ These tended to be verbal communications between two or more people and were equally as likely to be cross-disciplinary as intradisciplinary. They occurred with equal frequency in the pre-, intra-, and postoperative period, and the surgical attending physician was most often involved either as the transmitter or the receiver. Intraoperative field observations suggest that communication breakdowns and failures are pervasive in the operating room, occurring in up to one third of communication events.^{50,57}

Environmental and Organizational Factors

The importance of the structural characteristics of the system in which care is provided is underscored by the relation between variations in the frequency of risk-adjusted outcomes among institutions and differences in the systems of care in place within those institutions.⁵⁸ The substantial similarities between medical and nonmedical systems notwithstanding, the complex content and organizational structure of health care make it distinctive. Many system concepts that derive primarily from analyses of human-engineered, highly technical, nonbiologic systems may not be fully applicable to the more complex issues of patient safety.⁵⁹ Linearly engineered systems are likely to be far more predictable than biologic systems, in which appropriate processes do not always result in good outcomes. Patients frequently differ greatly from each other in terms of their ability to communicate relevant issues, their severity of illness, their comorbidities, and their responses to diagnosis and treatment. When a system is not expected to work perfectly at all times—as health care is not—it becomes more difficult to distinguish problems related to individual error from problems related to flaws in the system. This distinction between nonmedical mechanical systems and medical systems may be akin to the distinction between complicated and complex endeavors.⁶⁰

Differences in organizational structure between medical and nonmedical systems may be particularly relevant. A non-medical system is typically a single structure that is managed vertically through hierarchical control. Patient care, in contrast, tends to consist of numerous diverse subsystems that may be only loosely aggregated.⁶¹ These subsystems tend to function in isolation, and intrasystem changes tend to be managed laterally across individual subsystems. The resulting loose structure often leads to the creation of ineffective or even contradictory policies, all of which increase the chances of error.

The potential role of a systems approach in improving safety is further suggested by data that correlate improved outcomes with higher hospital or surgeon volume.^{62,63} Whether these findings are explained by “practice makes perfect” or by “perfect makes practice” is yet to be resolved, but in either case, it seems likely that the improved outcomes reflect better care systems. That some high-volume hospitals and surgeons have below-average outcomes and many low-volume hospitals and surgeons have excellent ones is consistent with the role of systems.⁶⁴

The physical characteristics of the system in which care is provided can influence the safety of the system. Issues such as ergonomics, lighting, equipment malfunctions, noise levels, and interruptions can increase the vulnerability to error and adverse outcomes.

A system’s results may be summed up as follows: “Whether your output is good or bad, it is, nonetheless, the only output of which your systems, processes, and methods are currently capable.”⁵⁹ Otherwise stated, every system is perfectly designed for the results it gets.

Lessons from Other High-Risk Domains

A systems approach to safety improvement has led to major advances in a number of other high-risk work environments, such as aviation and other transportation domains. As we start to understand health care as a system and the role of human factors in system performance, we can learn from the advances made in these other fields. Patterson and colleagues identified handoff strategies that were identified in other settings with high consequences for failure (space shuttle mission control, nuclear power, railroad and ambulance dispatchings) that could be applied to improve the safety of handoffs in health care [see Table 2].⁶⁵

Significant advances have been made in adopting the technique of crew resource management (CRM) from aviation to health care and surgery. CRM was first used by the aviation industry to improve airline crew coordination, and the IOM report *To Err Is Human: Building a Safer Health System* identified it as a strategy to reduce medical errors and improve patient safety.² Since this call for its implementation, the use of CRM has been evaluated in various health care fields, including operating room teams. In one study, teams underwent an 8-hour training course that covered six key areas of CRM: managing fatigue; creating and managing a team; recognizing adverse situations; cross-checking and communication techniques; developing and applying shared mental models for decision making; and giving and receiving performance feedback.⁶⁶ Although 95% of respondents agreed that the training would reduce errors in their workplace, cultural barriers still exist within surgery. Whereas only 26% of pilots denied that fatigue has a detrimental effect on performance, 70% of surgeons and 47% of anesthesiologists felt that they can perform effectively even when fatigued.⁶⁷ In the same study, only about half of attending surgeons favored a flat hierarchy in which junior members of a team could question decisions made by senior team members, whereas 94% of pilots advocated for this approach. Perhaps more broad adoption of CRM will help bridge this cultural divide.

Table 2 Handoff Coordination and Communication Objectives and Relevant Strategies⁶⁵

Improve handoff update effectiveness 1. Face-to-face verbal update with interactive questioning 2. Additional update from practitioners other than one being replaced 3. Limit interruptions during update 4. Topics initiated by incoming and outgoing team members 5. Limit initiation of operator actions during update 6. Include outgoing team’s stance toward changes to plans and contingency plans 7. Readback to ensure that information was correctly received
Improve handoff update efficiency and effectiveness 8. Outgoing writes summary before handoff 9. Incoming assesses current status 10. Update information in the same order every time 11. Incoming scans historical data before update 12. Incoming reviews automatically captured changes to sensor-derived data before update 13. Intermittent monitoring of system status while “on call” 14. Outgoing has knowledge of previous shift activities
Increase access to data 15. Incoming receives primary access to the most up-to-date information 16. Incoming receives paperwork that includes handwritten annotations
Improve coordination with others 17. Unambiguous transfer of responsibility 18. Make it clear to others at a glance which personnel are responsible for which duties at a particular time
Enable error detection and recovery 19. Overhear others’ updates 20. Outgoing oversees incoming’s work following update
Delay transfer of responsibility during critical activities 21. Delay the transfer of responsibility when concerned about status/stability

Approaches to Improving Patient Safety

Given the similarities between medical and nonmedical systems, it should not be surprising that many safety improvement techniques derived from nonmedical settings have been successfully applied in medical contexts [see Table 3].^{68,69} Other useful strategies include prioritization of tasks, distribution of the workload over time or resources, changing the nature of the task, monitoring and checking all available data, effective leadership, open communication, mobilization and use of all available resources, and team building.¹ The

Table 3 Nonmedical System Techniques Also Applicable to Medical Systems

Simplify or reduce handoffs Reduce reliance on memory Standardize procedures Improve information access Use constraining or forcing functions Design for errors Adjust work schedules Adjust the environment Improve communication and teamwork Decrease reliance on vigilance Provide adequate safety training Choose the right staff for the job
--

general idea behind many of these approaches is to redesign the problem space to reduce the cognitive workload.^{28,70}

A vital early step in improving patient safety is to establish a safety culture throughout the workplace. An important development in this area is the ability to make valid measurements of an organization's safety climate.⁷¹ An appropriate organizational culture views errors as signals for needed changes and focuses on learning rather than on accountability. If the team or organization is designed to learn from and benefit from experience, its collective wisdom should be greater than the sum of the wisdom of its individual members. Needed changes often involve difficult choices among strategic factors and sometimes introduce new latent flaws.^{37,72} Accordingly, once a change in procedure or policy has been implemented, its impact must be monitored closely.⁷³ New latent failures may result from either oversimplification³¹ or redundancy. As noted (see above), the latter enhances reliability, but its benefits are often offset by greater complexity and a consequent increase in the risk of human failure.³⁰ In addition, the more complex the system, the greater the chance that a change will have more than local effects. How to control some errors without relaxing control over others is a general problem in error management.^{30,74}

Good teamwork requires that team members share a clear understanding of what is happening and what should happen (i.e., situational awareness).³⁰ Unfortunately, there is a common tendency to believe that the prevailing level of situational awareness is greater than it actually is. For example, the aviation industry further improved its safety record when it identified and removed barriers that impeded junior officers from communicating with the captain. This achievement is noteworthy because these improvements took place after good communication was already thought to exist.⁷⁵

Even though physicians have increasing access to information technology in practice (www.hschange.org/CONTENT/891), physician acceptance of computerization has been neither easy nor universal, and medicine is far behind other industries in terms of the extent to which it has adopted such technology. Studies from the past few years suggest that only about one third of physicians receive any data (process data, outcome data, or patient surveys) about the quality of care they provide.⁷⁶ This finding may be partly explained by the cost of introducing information technology (which can become outmoded relatively quickly).

Another possible factor here is concern that caregivers might become too dependent on computerized advice-giving systems and thus might start making a habit of perfunctorily acceding to the computer's advice rather than trusting their own judgment. Issues of legal liability then arise: how much computer advice is too much, and is relying on such advice tantamount to abandoning responsibility for critical independent thought? A related concern is that many patient care tasks may be too complex for computerization and thus may be better suited to human performance. The tradeoff for retaining the human ability to deal with such complexity is the human susceptibility to error: systems that rely on error-free human performance are destined to experience failures. Because the kinds of transitory mental states that cause errors are both unintended and largely unpredictable, they are the last and least manageable links in the error chain.

A further approach to improving patient safety has been the development of specific tools and indicators for identifying common safety problems. Examples of these are the Patient Safety Indicators from the Agency for Healthcare Research and Quality (AHRQ) (www.ncbi.nlm.nih.gov/bookshelf/br.fcgi?book=techrev5) [see Table 4] and the serious reportable event list from the National Quality Forum (NQF) (www.qualityforum.org/Projects/s-z/SRE_Maintenance_2006/Fact_Sheet_-_Serious_Reportable_Events_in_Healthcare_2005-2006_Update.aspx) [see Table 5]. The lists are similar in some respects but not identical: the NQF further subcategorizes events into surgical events, product or device events, patient protection events, care management events, environmental events, and criminal events. Both lists specify clearly identifiable and readily measurable events, both include a variety of causes in addition to medical errors that lead to such adverse events, and both were developed by panels of experts. Yet a recent study indicated that, relative to risk managers, physicians were less aware of error-reporting systems in their hospitals or the adequacy of such mechanisms.⁷⁷

Techniques for Identifying System Flaws

Intensive examination of system flaws is most often triggered by a catastrophic failure or, less often, by a near miss. The appropriate investigation of such events is known as root cause analysis (RCA). The Joint Commission (formerly the JCAHO) (www.jointcommissioninternational.org/Books-and-E-books/Root-Cause-Analysis-in-Health-Care-Tools-and-Techniques-Fourth-Edition/1502) has a matrix for RCA, and experience with RCA in health care institutions has been reported.^{78,79}

In the case of an actual failure, the next steps are to identify all the relevant subsystems and to assemble a team whose members represent all of the components. Determining all of the components within a complex system can be challenging, and it may prove necessary to add members to the team as more subsystems are identified. In this regard, it is better to err on the side of inclusiveness rather than exclusivity to minimize the chances of missing latent flaws and maximize the number of possible solutions. Studies that relate nurse staffing to quality of care illustrate the important roles that

Table 4 Agency for Healthcare Quality and Research Patient Safety Indicators

Complications of anesthesia
Death in low-mortality diagnosis-related group
Decubitus ulcer
Failure to rescue
Foreign body left during procedure
Iatrogenic pneumothorax
Selected infections
Postoperative hip fracture
Postoperative hemorrhage or hematoma
Postoperative pulmonary embolism or deep vein thrombosis
Postoperative sepsis
Postoperative wound dehiscence
Accidental puncture or laceration
Transfusion reaction
Obstetric trauma

Table 5 National Quality Forum List of Health Care Facility–Related Serious Reportable Events

Category	Event
Surgical	A. Surgery performed on the wrong body part B. Surgery performed on the wrong patient C. Wrong surgical procedure on a patient D. Unintended retention of a foreign object in a patient after surgery or other procedure E. Intraoperative or postoperative death in an ASA class I patient
Product or device	A. Patient death or serious disability associated with use of contaminated drugs, devices, or biologics B. Patient death or serious disability associated with use or function of a device in patient care, in which the device is used or functions otherwise than intended C. Patient death or serious disability associated with intravascular air embolism
Patient protection	A. Infant discharged to the wrong person B. Patient death or serious disability associated with patient elopement (disappearance) C. Patient suicide or attempted suicide resulting in serious disability
Care management	A. Patient death or serious disability associated with a medication error B. Patient death or serious disability associated with a transfusion reaction C. Maternal death or serious disability associated with labor and delivery in a low-risk pregnancy D. Patient death or serious disability associated with hypoglycemia E. Death or serious disability associated with failure to identify or treat neonatal hyperbilirubinemia F. Stage 3 or 4 pressure ulcer acquired after admission G. Patient death or serious disability associated with spinal manipulative therapy H. Artificial insemination with wrong donor sperm or wrong egg
Environmental	A. Patient death or serious disability associated with electrical shock B. Any incident in which a line designated for oxygen or other gas to be delivered to a patient contains the wrong gas or is contaminated by toxic substances C. Patient death or serious disability associated with a burn incurred from any source D. Patient death or serious disability associated with a fall E. Patient death or serious disability associated with the use of restraints or bedrails
Criminal	A. Any care ordered by someone impersonating a physician or other licensed health care provider B. Abduction of a patient of any age C. Sexual assault of a patient D. Death or significant injury of a patient or staff member from a physical assault

ASA = American Society of Anesthesiologists.

other members of the health care team play in ensuring patient safety.^{80–82} In some situations, it may be difficult to generate interest in RCA because the circumstances are so unusual that they are unlikely ever to combine in the same way again.

Systems analyses in the presence of a near miss, or in the absence of any specific event, require a more global approach to help avoid future errors. Areas where such analyses might be fruitful include those identified by AHRQ [see Table 4], the NQF [see Table 5], and the Joint Commission. Another source for specific topics is AHRQ WebM&M (www.webmm.ahrq.gov), an AHRQ-developed Web site that provides expert analysis of medical errors in five specialty areas (including surgery), as well as interactive learning modules. AHRQ has also created extensive lists of other quality measures (www.qualitymeasures.ahrq.gov) and tools for improving patient safety. The next steps in this situation are to decide on measures for analysis and to identify appropriate data sources. Medical record audits yield far greater detail than claims data but are expensive, labor intensive, and time-consuming. Moreover, information on the environment or behavior in medical records may be irrelevant or even contradictory. This problem can sometimes be mitigated by employing appropriate screening criteria.⁸³ Some of the shortcomings of medical record audits can be avoided by using administrative data, but such data often lack sufficient accuracy or depth. Electronic health records can potentially simplify this process

and possess a number of other advantages.^{84,85} RCA can be automated,⁸⁶ but the potential advantages of doing so may be offset by a dependence on the developer's interpretation of the risk reduction process or by the factors identified as the principal event.

Regardless of the data source, the process is likely to be evolutionary: rarely is a perfect set of measures available from the start. Although the findings from such an analysis might seem to offer little benefit to the institution in which they occurred, such incidents may occur frequently enough at a regional or national level to make the analysis worthwhile.

Other analyses associated with successful quality improvement efforts include patient notification systems,⁸⁷ patient safety systems,⁸⁸ analyses of system failures in laparoscopic surgery,⁸⁹ and analyses of medical microsystems.⁷² Critical analyses of evidence-based practices also identified 11 surgically relevant quality improvement practices for which the data were strong enough to support more widespread implementation [see Table 6].^{90,91} A note of caution that should be sounded here is that exclusive emphasis on evidence-based data could skew safety priorities and might actually prevent relatively few adverse events.⁹² Another potential area for review involves changes in policy or equipment that might introduce unanticipated problems or unexplained variations in a relevant outcome measure. Every change in a system necessitates a new learning cycle, and the new environment may be conducive to failures from new latent errors.⁹³

Table 6 Surgically Relevant Quality Improvement Practices Appropriate for Widespread Implementation⁹⁰

Appropriate use of prophylaxis to prevent venous thromboembolism in patients at risk
Use of perioperative beta blockers in appropriate patients to prevent perioperative morbidity and mortality
Use of maximum sterile barriers while placing central venous catheters to prevent infection
Appropriate use of antibiotic prophylaxis to prevent postoperative infections
Requesting that patients recall and state what they have been told during the informed consent process
Continuous aspiration of subglottic secretions to prevent ventilator-associated pneumonia
Use of pressure-relieving bedding materials to prevent pressure ulcers
Use of real-time ultrasound guidance during central line placement to prevent complications
Patient self-management for warfarin to achieve appropriate outpatient anticoagulation and prevent complications
Appropriate provision of nutrition, with particular emphasis on early enteral nutrition in critically ill and surgical patients
Use of antibiotic-impregnated central venous catheters to prevent catheter-related infections

Successes and Obstacles to Success

In view of the complexities of health care, taking a systems approach to safety improvement may seem a daunting endeavor. Nevertheless, there are a number of cases in which this task has been successfully accomplished. For the purposes of illustration, it is worthwhile to review these examples briefly.

Anesthesiologists were among the first physicians to take a systems approach to patient safety, and their success is irrefutable: anesthesia-related mortality fell from approximately two in 10,000 to the current one in 200,000 to one in 300,000⁹⁴⁻⁹⁶—a degree of safety approaching that advocated for nonmedical industries (i.e., < 3.4 defects or errors/10⁶ products or events).⁹⁷ This improvement primarily resulted from a broad effort involving teamwork, practice guidelines, automation, simplification of procedures, and standardization of equipment and many functions. For instance, before the anesthesiologists' safety initiatives, design standards for anesthesia machines did not exist. As a result, it was not unusual to have one machine in which turning a valve in a given direction would increase gas flow and other machines in which turning it in the same direction would decrease flow; in fact, both types might be present in the same hospital. Equipment manufacturers subsequently worked together to standardize anesthesia equipment, and these kinds of arbitrary design variations are no longer seen.

The experience with safety efforts in anesthesiology underscores the importance of understanding the human-technology interface and the ergonomics of equipment design.⁹⁸ To improve patient safety, it is necessary to understand the devices and techniques employed, the ways in which individual persons use the technology, and the means by which these users interact with other aspects of the system.^{98,99} Similar considerations should be applied to innovative practices.¹⁰⁰

Another example is the recent high-profile application of procedural checklists. These checklists serve as the cornerstone of system-based interventions aimed at improving safety. A Michigan-wide collaborative targeting best practices around central line placement markedly reduced the morbidity and mortality associated with central lines in an intensive care setting.¹⁰¹ A surgical safety checklist implemented in eight international hospitals similarly was associated with a decrease in death and complications from nonpediatric surgical procedures.¹⁰² A number of different mechanisms may underlie the association between the checklists and improved outcomes, including better communication, less reliance on individual knowledge and memory, and increases

in situational awareness and a shared mental model; however, whatever the mechanism, the use of checklists, adopted from aviation, changes the system in which care is delivered and the behavior and interactions of the team and individual practitioners.

Another emerging success is the use of technological adjuncts in the tracking of surgical sponges. The traditional approach to preventing retained objects following surgery depends on several members of the surgical team manually counting every item that is introduced onto the sterile field and again at the end of the operation. These protocols have been shown to be labor intensive as well as unreliable.¹⁰³ Seventy to 88% of cases of retained surgical equipment are associated with a correct count.⁹ The recognition that manual counts will not be sufficient to completely ameliorate retained objects after surgery, making it a true “never event,” has led to the development of several technological solutions. Radio-frequency identification tags and bar codes are two examples of such solutions. A randomized, controlled trial suggests that bar-coding sponges can improve the ability to track sponges during an operation.¹⁰⁴

These examples of success are encouraging, but considerable obstacles to improving patient safety still exist. Specific obstacles include (1) a residual lack of awareness that a problem exists; (2) a traditional medical culture based on individual responsibility and blame (and shame); (3) a perceived vulnerability to legal discovery and liability; (4) primitive medical information systems; (5) the time and expense involved in defining and implementing evidence-based practice; (6) inadequate resources for quality improvement and error prevention; (7) the local nature of health care; and (8) the perception of a poor return on investment (i.e., the lack of a business case).¹⁰⁵ Although the need to redefine health care on the basis of value seems obvious, the current environment still appears to focus primarily on cost; value (i.e., quality per unit cost) is not part of the equation.¹⁰⁶

One hindrance to improving patient safety is the idea that traditional improvement methods are adequate to address the problem. The persistence of patient safety problems in the face of the ongoing use of these methods should be a sufficient argument for the inadequacy of existing approaches. For instance, morbidity and mortality (M & M) conferences are perhaps the most traditional venue for discussion of adverse events, but they often do not consider all complications, are not consistently well attended, do not categorize complications systematically, and often do not involve extensive debriefing.^{37,107-109} One study that compared NSQIP with traditional M & M conferences noted that the latter failed to consider about 50% of the deaths and about 75% of the

complications.¹¹⁰ Furthermore, M & M conferences tend to be intradepartmental and thus provide little opportunity for discussion of system problems that involve other departments (e.g., anesthesiology or nursing). M & M conferences also typically do not consider near misses (i.e., close calls), even though such events can identify important actual and potential system flaws. Finally, M & M conferences have a tradition of focusing on the actions of individuals rather than on the circumstances within which the individuals acted. This tradition serves to perpetuate a defensive attitude among trainees that is counterproductive. It is possible, however, that a more systematized review process could improve the value of the M & M conference.^{111,112}

Joint Commission accreditation of hospitals is based on analyses of safety and quality information (www.jointcommissionreport.org). However, it has been observed that the Joint Commission's accreditation program lacks the ability to identify many patient safety problems.¹¹³

Peer review organizations were originally intended as a mechanism for professional self-evaluation but subsequently became subject to anticompetitive abuse and other undesired consequences.¹¹⁴ The potential for inequity was a particular concern in that physicians who relinquished privileges on their own initiative might be treated more leniently than those against whom action was initiated by a peer review committee. Moreover, the data reviewed by peer review organizations were often legally discoverable, and this lack of anonymity and confidentiality tended to deter voluntary participation. Even when peer review organizations identified problems, they were often unable to implement solutions. Peer review organizations have now been largely supplanted by quality improvement organizations, although it is not yet clear whether the latter are substantially more effective.^{115,116}

Hospital incident reports have much the same shortcomings as the peer review process. They place limited emphasis on close calls and tend to lack systematic follow-up. Individuals also may be reluctant to file reports out of fear that their employment might be jeopardized or that the reported party might seek retribution.

The present professional liability system is particularly controversial with respect to whether it facilitates or hinders improvements in patient safety. This system has its basis in the traditional paradigm of surgical care (see below), which holds the individual surgeon accountable as the "captain of the ship." This paradigm has enabled many great achievements in surgical care, but it has also probably fostered a dangerous sense of infallibility. As a consequence, errors tend to be equated with negligence, and questions of professional liability tend to involve blaming individuals. Indeed, the very willingness of professionals to accept responsibility for their actions makes it convenient to focus more on individual errors than on collective ones²²; an individual surgeon is a more satisfactory target for the anger and grief of a patient or family than a faceless organization would be. This is certainly not to say that surgeons should avoid responsibility; rather, the point is that focusing on the errors of individual surgeons without addressing flaws in the underlying system does little to improve health care.

Another notable flaw in the liability process is that judgments of causality or fault are vulnerable to hindsight bias, which can skew experts' assessments of quality of care.

This tendency was illustrated by a study of anesthetic care in which differences in outcome significantly influenced the perception of negligence, even when the care provided was equivalent.¹¹⁷ Hindsight bias focuses too narrowly on adverse outcomes and pays insufficient attention to the processes of care. Yet another defect of the liability process is that it can be emotionally devastating for physicians (and their families),^{118–120} often adversely affecting their problem-solving abilities. To the extent that experience with or fear of a liability action deters efforts at quality improvement, it is counterproductive. Defensive medicine, with its attendant costs, adds very little value to health care.¹²¹

Many believe that major reform of the professional liability system is a prerequisite for achieving any significant improvements in quality. Undoubtedly, tort reform is highly desirable; however, the real prerequisite for improving identification and correction of system failures is the provision of increased protection for privileged discussion of such failures. The federal Patient Safety and Quality Improvement Act of 2005 (Public Law 109-41) was enacted for the purpose of improving patient safety by encouraging voluntary and confidential reporting of events that adversely affect patients. This act creates patient safety organizations whose goal is to collect, aggregate, and analyze confidential information reported by health care providers. It also calls for establishing a network of patient safety databases as an interactive, evidence-based management resource. The act limits the use of this information in criminal, civil, and administrative proceedings and includes provisions imposing monetary penalties for violations of confidentiality or privilege protections. The notion that a reduction in liability concerns may facilitate disclosure and discussion of mistakes is suggested by international comparisons of health care systems. In one study, patients in New Zealand, which has no-fault medical malpractice, were the most likely to report error discussions with their physicians.¹³

It is to be hoped that the tort reform movement and the patient safety movement can seek and find common ground.¹²² The improvements in patient safety achieved by anesthesiologists speak for the benefits of such an approach. Instead of pushing for laws to protect them against patients' lawsuits, anesthesiologists focused on improving patient safety. As a result, they pay less for malpractice insurance today, in constant dollars, than they did more than 20 years ago.¹²³

Even before the enactment of the Patient Safety Act, the view that open discussion of medical errors was appropriate appeared to be gaining adherents.²¹ Today, there is even more evidence that such open communication may reduce the likelihood of legal action and enhance public confidence in health care providers.^{124,125} Unfortunately, some hospitals persist in separating risk management from quality assurance issues, to the detriment of both.¹²⁶

The obvious need for liability reform notwithstanding, there are issues involved in enhancing safety and quality that are too complex to be addressed solely by changes in the liability system. Major safety and quality problems exist in nations where professional liability is not an issue; however, the higher rates of adverse events in these countries should not be taken as evidence of the benefits of the current US liability system. Physicians tend to act defensively even in a no-fault liability system. To minimize such defensiveness,

greater emphasis must be placed on measurement for improvement than on measurement for judgment.¹²⁷

Changing the Traditional Surgical Paradigm

Contemporary surgical practice requires that surgeons rethink the traditional paradigm of surgical practice (see above). The burgeoning growth of knowledge, the accompanying increase in specialization, the expanding role of technology, and the rising complexity of practice are making surgeons more and more dependent on persons or factors beyond their immediate control. As a result, surgeons are finding it more and more difficult even to appreciate, let alone manage, the larger context within which they provide care. The traditional surgical paradigm, despite its past successes, is no longer entirely adequate to the task now at hand [see Table 7].¹²⁸ Paradoxically, surgeons seeking to improve patient safety must acquire a deeper understanding of patient care systems at the very time when those systems are becoming increasingly difficult to understand.

To achieve the requisite understanding, it is necessary to have a reporting system that collects, tabulates, and analyzes data on the frequency and nature of both adverse events and near misses.¹²⁹ The primary function of a patient safety reporting system should be to identify both real and potential adverse consequences of latent flaws and make them visible to others. Once these real and potential adverse events are identified and made visible, the system can be redesigned so as to eliminate or minimize them.

A successful reporting system such as the highly successful Aviation Safety Reporting System (ASRS) is typically nonpunitive, confidential (and preferably anonymous), independent, timely, systems oriented, and responsive.^{22,88,130} In addition, it includes expert analysis, meaning that reports are evaluated by persons who understand the relevant circumstances and are trained to recognize underlying system-based causes. A successful reporting system usually also tabulates seemingly rare incidents (including near misses) even if there seems to be little direct or immediate benefit to doing so; in addition to their potential value in larger contexts, such analyses may help institutions predict and thereby avoid errors and system failures. The absence of a punitive focus reduces health care workers' concerns that reports might be used against them and thus minimizes underreporting.^{36,131,132} The concerns about the possible adverse consequences of a reporting system are quite strong—so much so that many

believe that a health care reporting system can succeed only if legal immunity is available.¹³³ The fear of being sued is widespread among physicians; however, the perceived risk of being sued is three times greater than the actual risk, and there is no good correlation between hospitals' claims ratings and their injury rates.⁷²

A mandatory, anonymous, confidential, and nondiscoverable reporting system has been instituted in the state of Pennsylvania. Founded in 2003, the Pennsylvania Patient Safety Reporting System, a statewide database maintained by the Pennsylvania Patient Safety Authority, collects over 200,000 annual reports of near miss and adverse events. (<http://patientsafetyauthority.org>). The events are evaluated, summarized, and analyzed to identify patterns that can be used to develop patient safety solutions and interventions.

Whether such reporting should be voluntary or mandatory is still a matter of debate. On the one hand, voluntary reporting has a high inaccuracy rate even when mandated by state or federal regulations. On the other hand, many surgeons believe that mandatory reporting may increase the pressure to conceal errors rather than analyze them; that it is unworkable in the current legal system; and that it may result not in constructive error-reducing solutions but merely in more punishment or censure.¹³⁴

Some argue that patient safety efforts should focus (at least initially) on medical injury rather than on medical errors.^{135,136} A focus on medical injury recognizes the difficulties of identifying medical errors and is based on a public health improvement model that has been useful in addressing other types of injuries; it also recognizes that most medical injuries are not caused by negligence. Such an approach may be more compatible with the current liability system and may help restore physicians' stature as patient advocates. Moreover, placing the initial focus on medical errors rather than injuries might divert attention from other system flaws, with the result that such flaws go uncorrected. Although, ultimately, a successful reporting system must focus both on errors and on injuries, an initial focus on injury may achieve greater initial buy-in from surgeons and may therefore be a more pragmatic first step. The issues associated with reporting errors or injuries must also be distinguished from those associated with reporting outcomes to the public. The latter type of report is currently being seen with increasing frequency, but it may have unintended consequences.¹³⁷

The complexities involved in understanding and improving health care systems make it likely that patients' expectations of improved safety may grow faster than they can be met.^{138,139} This potential disparity between expectations and performance may be further exacerbated by the likelihood that errors have been substantially underreported.¹⁴⁰ A reporting system that is punitive or not anonymous may discourage appropriate reporting of medical errors. Underreporting of adverse events is also more likely if side effects are delayed or unpredictable, if there is a longer survival or latency interval, or if a patient has been transferred from one facility to another. In addition, inadequate doses of drugs or anesthetics may not be reported if they cause no immediately evident injury.

Another challenge facing surgeons is how to incorporate current concepts of performance and error into undergraduate and residency education.¹⁴¹ The optimal basis for such education might be an objective-based curriculum that

Table 7 Contrasting Characteristics of Medical Practice in the 20th and 21st Centuries¹²⁹

Change

provides defined skills, rules, and knowledge.^{142,143} The blame-and-shame approach must be eliminated from both the educational setting and the practice atmosphere. If, instead, educators focus on making residents aware of their tendencies in the presence of uncertainty, residents (like pilots) may be able to develop better responses to underspecified situations. In addition, it is vital to monitor the residents to ensure that they learn to assess and address knowledge deficits, as well as acquire healthy and effective techniques for dealing with errors. Such monitoring will make the learning curve less painful for all concerned.¹⁴⁴

There is some question as to whether safety improvements are more likely to result from compliance with standards (i.e., individual performance) or from improvements in the system. Better training of individual physicians will certainly improve performance, but only so far. For substantial improvements in safety, it is probably necessary to make use of both approaches.¹⁴⁵ If every system is perfectly designed to achieve the results it gets, the obvious conclusion is that to obtain the desired results, it is necessary to change the system. Determining what form the new system should take is a critical step.^{106,146}

Conclusions

Reducing adverse events during the course of medical care is a dauntingly complex topic, and the progress made in reducing such errors has, in many cases, been disappointingly slow. Roughly a century ago, surgeons were called on to report their results, but over the intervening years, this call largely went unheeded.¹⁴⁷ It must be said, however, that at the beginning of the 20th century, the basic principles of human performance and error were not as well understood as they currently are, and the tools necessary for systems analysis did not exist. A further difference between then and now is the increase in public awareness of safety issues, as well as the potential consequences of this awareness.^{13,148} For instance, the growing concern about safety is changing the way in which patients select providers: there has been a

substantial increase in the percentage of patients who would choose a highly rated surgeon whom they had not seen before over a less highly rated surgeon whom they had seen before (www.ahrq.gov/qual/kffhigh00.htm). Improving patient safety thus becomes a matter of self-interest for the provider. It also may have a direct bearing on the maintenance of physicians' social contract with their patients.

The systems approach to improving patient safety is based on three principles: (1) human error, as an inherent aspect of human work, is unavoidable; (2) faulty systems allow human error to injure patients; and (3) systems can be designed that prevent or detect human error before such injuries occur.^{149,150} Support for a systems approach to patient safety will come from patients, purchasers from both the public and the private sector, professional societies, and specialty boards.¹⁵¹ It is crucial for all of these parties to acknowledge that most medical errors are attributable to system flaws rather than incompetence or neglect. It is also essential to recognize that the current systems of surgical care are shaped by the larger system within which all of these parties interact. This means that any worthwhile effort to improve such systems is likely to require substantial collaboration among the parties involved,¹⁵² as well as significant change in the larger system.

Medical errors have a substantial impact on 90-day costs and outcomes of surgical patients.¹⁵³ Moreover, there appears to be a business case for investing in patient safety.¹⁵⁴ Physicians, with their history of patient advocacy and scientific innovation, are in the best position to provide the leadership necessary for such changes.^{87,155} To restore the public's trust in the health care system, safety and quality must be made high priorities,¹⁵⁶ and transparency must be ensured.¹⁵⁷ If physicians do not take the opportunity to lead the movement to improve the safety and quality of care, they may anticipate further erosion of public trust and further loss of professional autonomy.

Financial Disclosures: None Reported

6 PREOPERATIVE TESTING, PLANNING, AND RISK STRATIFICATION

Randi Smith, MD, Valerie Ng, MD, PhD, Patrick Twomey, MD, and Alden H. Harken, MD*

In most circumstances in medicine, diagnosis precedes treatment. Consensus statements and regulatory guidelines endorse the long-hallowed practice of identifying patients at increased risk for complications. This is called “prognostic testing.” The implication is that the benefit of special risk reduction strategies should be confined to these patients. Most of the cardiovascular (and pulmonary) “screening” tests considered below are of the prognostic type only.

Much more useful than prognostic testing is predictive or directive testing, which means identifying patients who will benefit from a specified, available intervention. By definition, this discriminates a subset of “bad prognosis” patients who can be helped and thus requires the existence of a therapeutic intervention of demonstrated benefit. This often includes identifying those patients who are not too ill but not too well to benefit from the associated therapy.

Proof that a testing strategy is predictive, not merely prognostic, is best demonstrated by randomized trials comparing outcomes in groups receiving best conventional care with or without the proposed test. This is a high standard but has been met in situations such as screening mammography for breast cancer in women ages 50 to 70 and computed tomographic (CT) scans in closed-head injury.

In medicine and surgery, we like to think of ourselves as scientists who make decisions and perform procedures based on the results of studies and clinical trials that support our management strategies. Traditionally, we always obtain a clinical history and perform a physical examination. This interaction with our patients helps us focus and refine our therapies but, equally importantly, promotes the health literacy of our patients.¹ There is good evidence that patients who understand their disease and who participate actively in their therapy will fare better.¹

However, once we have finished talking with our patients, the data-driven support for the traditional model of preoperative testing begins to break down. We define a “routine test” as a test that we obtain on an asymptomatic, apparently healthy patient in the absence of any specific clinical indication.² Then we examine the frequency of abnormal routine test results, but it gets cloudier when we try to determine how often an abnormal test result changes our management. There is almost no information relating a test-driven alteration in management to any benefit in outcome. Intuitively, we do know that the more fragile the patient and the bigger the surgical procedure, the more likely it is that we should anticipate trouble.

* The authors and editors gratefully acknowledge the contributions of the previous authors, Cyrus J. Parsa, MD, Andrew E. Luckey, MD, Nicolas V. Christou, MD, to the development and writing of this chapter.

Financial disclosure information is located at the end of this chapter before the references.

In addition to functional capacity and comorbid conditions, age is a robust determinant of operative risk, as is the type of operation. Vascular procedures and prolonged, complicated thoracic, abdominal, or head and neck procedures carry higher levels of risk. None of this is surprising.

The purposes of this chapter are as follows:

1. To explore the tools available to the surgeon for assessing patient vulnerability to operative stress
2. To examine the practical specifics of preoperative functional status testing
3. To analyze methods of quantifying surgical stress
4. To develop patient status and operative insult-specific indications for some “routine” preoperative tests
5. To suggest some strategies to reduce risk in specified groups of patients

Preoperative Laboratory Testing

There are at least 33 reasons why surgeons order preoperative laboratory tests; some are unique to teaching environments, and most are not clinically useful or relevant in the “otherwise healthy patient in the absence of a specific indicator.”³ There is poor correlation between the number of tests ordered and quality of care or physician competence, and the wide variation in test ordering suggests that some, or perhaps many, tests are ordered unnecessarily.⁴

As a corollary, surgeons order preoperative laboratory tests for fear of malpractice, for detection of an unsuspected disease, or because they “have always done it that way.” Note that detecting an unsuspected disease in the preoperative period is no different from screening for disease in a population, albeit a selected (preoperative) population.

Comprehensive literature reviews and government publications guiding reimbursement for preoperative testing (or lack thereof)^{2,5,6} lament the lack of Level I evidence to guide policy making, but most admit that the preponderance of nonrandomized clinical trial data demonstrates that preoperative testing is not clinically useful. Amazingly, this question has been studied formally for at least 50 years (yes, half a century), with the following strikingly similar conclusions. Preoperative laboratory testing

1. Has no clinical value for asymptomatic healthy individuals, in the absence of a specific clinical indication, such as a diuretic
2. Has only marginal value for those with known disease
3. Will yield abnormal results for 1 to 2% of all test results
4. Yields results that would have been predicted from the underlying patient diseases
5. Does not change treatment when abnormal results are obtained
6. Yields abnormal results that are often ignored by the ordering physician
7. Allows considerable unrealized cost savings derived from not performing these preoperative tests

So let us chronologically recapitulate selected studies chosen to demonstrate the evolution of this issue through the lenses of multiple medical specialties. In 1965, pathologists Bold and Corrin published their study titled "Use and Abuse of Clinical Chemistry in Surgery."⁷ This study was performed in the early days of clinical pathology, before automated analyzers were commercially available. One hundred fifty of 344 (44%) tests were preoperative tests of "urea and electrolytes and metabolic abnormalities in patients with renal calculi." Almost all of the preoperative test results were within accepted reference ranges and were euphemistically termed "useful negative" results. This study pioneered the acquisition of nonuseful preoperative laboratory data.

Automated clinical laboratory testing became widely available in the late 1960s, exponentially increasing the opportunity for unnecessary laboratory testing. In the early 1980s, several groups assessed preoperative laboratory testing (they termed it "screening") for 2,000 patients. Many tests were ordered "by protocol," including complete blood count (CBC), white blood cell (WBC) differential, prothrombin time (PT), partial thromboplastin time (PTT), platelet count, "six-factor automated multiple analysis" (sodium, potassium, chloride, total carbon dioxide content, serum urea nitrogen, creatinine), and glucose. Of 2,785 routine preoperative admission tests, the authors concluded that approximately 60% were "unindicated" (i.e., the patient lacked a recognizable clinical indication for testing). Four results (0.22%) were substantially significant so as to affect anesthetic or surgical management, yet there was no documentation that care management was altered based on these abnormal laboratory results. Furthermore, there was no documentation by physicians of further exploration of these abnormal results, presumably raising (rather than limiting) issues of legal liability for the ordering physician. The authors concluded that preoperative testing should be performed only for patients with an identified disease or for whom the surgical procedure would be altered based on the result. They extrapolated that approximately 9,000 tests annually could have been avoided, resulting in approximately \$147,000 decreased charges and a cost savings of \$95,800 (1985 dollar value).

Physicians and surgeons are perhaps guilty of a certain amount of intellectual inertia as similar studies paradoxically concluded that preoperative testing was "useful" even when the authors acknowledged that test abnormalities provoked no clinical consequences. A consistent finding was a 1 to 2% incidence of abnormal results, a lack of clinical consequences, and an absence of physician response to the abnormal laboratory tests.

Anesthesiologists have been the first discipline to substantively engage in the debate. When managed care capitation was introduced and cost containment became critical to the survival and success of health care organizations, anesthesiologists were the first group to responsibly respond. Allison and Bromley assessed the clinical usefulness of preoperative testing in 60 randomly selected veterans prior to ambulatory surgery.⁸ They concluded that two thirds of testing was inappropriate and estimated the unnecessary costs at \$47 for a veteran and \$80 for a community hospital patient (1996 dollar value), with potential savings of \$11,757

for their Veterans Affairs Medical Center alone. They concluded that preoperative testing limited exclusively to those patients with clinical indications would have no effect on the quality or safety of care.

In a similar study of 520 patients undergoing elective general, vascular, thoracic, and head and neck surgery, preoperative tests included electrolytes, blood urea nitrogen (BUN), creatinine, glucose, hemoglobin/hematocrit, total protein, albumin, total lymphocyte count, PT, PTT, platelet count, urinalysis, electrocardiography (ECG), and chest radiography.⁹ Age, gender, and specific concomitant illnesses were associated with predictably abnormal laboratory tests. Routine preoperative laboratory testing was identified as "neither useful nor cost-effective." Perhaps in response to this wave of data, preoperative testing practice at four institutions over 8 years and for only four surgical procedures was examined. Although wide variations from "operation to operation, test to test and institution to institution," were unexpectedly identified, an approximately 20% decrease in both unnecessary and medically indicated testing was achieved. For the unnecessary tests alone, the authors extrapolated to the entire United States and estimated an approximately \$320 million annual savings.

The obvious question is what happens to patients who do not enjoy the safety of preoperative laboratory testing? Narr and colleagues reviewed the outcomes of 1,044 randomly selected patients from 5,120 patients who had no laboratory tests performed within 90 days before a surgical procedure.⁹ Ninety-seven percent of the patients were "relatively healthy." Zero deaths or major perioperative complications resulted. Furthermore, this group observed that no laboratory test performed intra- or postoperatively changed surgical or medical management "substantially." They concluded that patients who, following a history and physical examination, are "determined to have no preoperative indication for laboratory tests can safely undergo anesthesia and operation with tests obtained only as indicated intra- and postoperatively."

In 1995, laboratory medicine, surgery, and anesthesia practitioners collaborated to develop laboratory testing guidelines before admission for elective surgery.¹⁰ Testing guidelines were developed and categorized into four major groups, as well as by age and gender. The surgeons then agreed to delegate test ordering to nurses and anesthesiologists who evaluated the patients before surgery. Volume and appropriateness of ordered tests were compared before and after guideline adoption. They observed a 67% reduction in the overall number of tests ordered per patient for the first 2 years after guideline implementation, with an improvement in the appropriateness of test ordering (65% were considered "appropriate" prior to guideline implementation and 81 to 86% postimplementation). They noted marked fiscal savings related to this performance improvement initiative, quantified as \$66,981 in year 1 and \$75,995 in year 2.

In the late 1990s, anesthesiologists Vogt and Henson conducted a prospective, cross-sectional study in a university hospital, studying 312 consecutive patients scheduled for elective surgery and evaluated by an anesthesiologist in a preoperative clinic.¹¹ **The goal of the study was to determine if there was a difference in the ordering of "unindicated**

preoperative laboratory tests" for healthy (American Society of Anesthesiologists [ASA] physical status I and II) versus sicker (ASA physical status III) patients. The anesthesiologists evaluated the test ordering by surgeons relative to ASA status and concluded that 72.5% of tests ordered by surgeons were considered not indicated by the anesthesiologists. Although there were fewer "unindicated" tests with worsening ASA status, the overall conclusion was that a large proportion of surgeon-ordered preoperative tests were unnecessary. By eliminating unnecessary testing, they estimated an annual cost savings of \$80,000 (1997 dollars).

In 2002, the ASA Task Force on Preanesthesia published its review and practice advisory.⁵ Regarding laboratory tests, a clear distinction was made between "routine" and "selective" preoperative tests. Routine tests were defined as those intended to discover a disease or disorder in an asymptomatic individual. The task force bluntly stated that routine tests "do not make an important contribution to the process of perioperative assessment and management of the patient by the anesthesiologist." In contrast, the task force recommended performing selective tests, that is, those tests medically indicated because of the history and physical findings, medical record review, and type of invasiveness of the planned procedure and anesthetic, because their results "may assist the anesthesiologist in making decisions about the process of perioperative assessment and management."⁵ Clinical studies are very hard to do, and it is easy to criticize them. Perhaps these studies were performed in settings where timely treatment of chronic diseases was available, allowing maximal optimization of patients prior to elective surgery. The recommendations of a conscientious task force are difficult to ignore, however. So what happens to surgical patients in developing countries where no chronic disease management is available?

Pal and colleagues retrospectively studied the benefit of preoperative testing in 216 asymptomatic healthy surgical patients in Pakistan.¹² Their findings were strikingly similar to those of previous studies; the most common preoperative laboratory abnormality was a low hemoglobin in 42 of 216 (19%) patients, almost all females. Chest x-ray abnormalities were the next most common abnormality, present in 11 of 103 (10.6%) patients, followed by mild hypokalemia in 6 of 123 (4.8%) patients and an elevated glucose in 1 of 113 (0.88%) patients. Aside from a single preoperative intervention for a patient with a preoperative hemoglobin of 4.8 g/dL, treatment plans or outcomes were not affected. The authors concluded that the history and physical examination were the most reliable and cost-effective preoperative screening tools available. They endorsed the existing ASA guidelines for class I (asymptomatic healthy) patients, that is, no preoperative testing is recommended.

In 2003, the general medicine and primary care practitioners entered the debate. Smetana and Macpherson reviewed the published literature on preoperative testing and concluded that "almost all 'routine' laboratory tests before surgery have limited clinical value."¹³ Based on their review, they recommended the following:

- "Clinicians should order tests only if the outcome of an abnormal test will influence management."
- "When an abnormal test results from such testing, it is critical that physicians document their thinking about the result."

- "Physicians should not be criticized for selective test ordering before surgery."
- "Physicians and institutions recommending routine preoperative testing for all patients provide no clinical value to their patients at considerable cost."

A subset of studies have noted specific abnormal laboratory results related to age, gender, and concomitant underlying illnesses. The latter, selective testing for concomitant underlying illnesses, is accepted practice for routine medical care regardless of anticipated surgery. The common theme appears to be that if the physician would request a test in the absence of anticipated surgery, the test is also warranted prior to surgery. Extremes of age and gender do keep reappearing as potential independent predictors of trouble.

AGE

Dzankic and colleagues assessed the importance of preoperative laboratory testing in 544 patients 70 years and older undergoing noncardiac surgery.¹⁴ They observed that 0.5 to 5% had electrolyte and platelet count abnormalities, 12% had elevated serum creatinine (> 1.5 mg/dL), 10% had hemoglobin less than 10 g/dL, and 7% had serum glucose greater than 200 mg/dL. None of these abnormalities were predictive of postoperative adverse outcomes. The ASA classification and surgical risk were stronger univariate predictors for adverse outcome than abnormal serum electrolyte or creatinine values, and only the ASA classification and surgical risk by multivariate logistic regression were predictive of postoperative adverse outcomes. The authors concluded that age alone was not sufficient justification for routine preoperative laboratory testing and recommended using the history and physical examination to guide preoperative testing.

Ophthalmologists Schein and colleagues conducted a landmark study of 9,408 patients aged 80 years and older who underwent 9,626 cataract surgeries without preoperative testing, compared with 9,411 patients undergoing 9,624 operations who had routine preoperative laboratory testing.¹⁵ They found no difference between groups relative to intraoperative or postoperative events. Routine preoperative testing offered no benefit over that attained from ASA classification and medical history. They concluded that routine preoperative testing before cataract surgery did not measurably increase the safety of surgery.

Schein and colleagues noted that cataract surgery was the most commonly performed operation in elderly people in developed countries, with 1.5 million cataract operations in 1996.¹⁵ From their study, it was estimated that the cost of routine preoperative testing prior to cataract surgery exceeded \$150 million annually and, given the lack of benefit from testing, suggested that these costs could be saved without a negative effect on patient outcome.

The screening value of preoperative laboratory findings in children is the same as that for adults: not clinically useful for healthy children presenting for minor elective surgery. Burk and colleagues encouraged preoperative coagulation testing to identify rare, undiagnosed congenital or hereditary bleeding disorders in children prior to tonsillectomy.¹⁶ This value, however, was clearly offset by the rarity of the disorders coupled with the high frequency of false positive bleeding histories and laboratory tests.

GENDER

A relatively common finding in many preoperative testing studies was anemia in women of childbearing age. This is the only gender-specific “abnormality” reported and would support preoperative inquiry if the clinical presentation would prompt the clinician to respond to an abnormal result.

Several decades ago, a group at the Mayo Clinic began to realize that subjecting patients to large numbers of preoperative tests did not change surgical results.^{17,18} They further observed that when preoperative testing returned an abnormal result, they rarely did anything differently anyway¹⁷ [see Table 1 and Table 2].

In summary, the overwhelming majority of studies have concluded that there is little to no value of screening preoperative laboratory tests in asymptomatic patients in the absence of a specific clinical indication [see Table 3]. Laboratory tests within 6 months of surgery to gauge surgical and anesthesia risk are acceptable if the patient’s condition has not changed clinically in the intervening period. Conversely, if the patient’s condition has changed, laboratory

Table 1 Effect of Abnormal Screening Results on Physician Behavior ¹⁸		
Screening Test	% Abnormal Test Results	% Resulting in Management Change
Bleeding time	3.8	Abnormal result rarely led to change
Chest x-ray	2.5–3.7	2.1
Coagulation time	4.8	Abnormal result rarely led to change
Electrocardiogram	4.6–31.7	0–2.2
Hemoglobin	5 (for < 10 g/dL; < 9 g/dL was rare)	Abnormal result rarely led to change
Partial thrombo-plastin time	15.6	Abnormal result rarely led to change
Total leukocyte count	< 1	Abnormal result rarely led to change
Urinalysis	1–34.1	0.1–2.8

Table 2 Minimum Preoperative Test Requirements at the Mayo Clinic (in 1993) ¹⁷	
Age (yr)	Tests Required
< 40	None
40–59	Electrocardiography, measurement of creatinine, measurement of glucose
≥ 60	Chest x-ray, complete blood cell count, electrocardiography, measurement of creatinine, measurement of glucose

In addition, the following guidelines apply: (1) a complete blood cell count is indicated in all patients who undergo blood typing and are crossmatched; (2) measurement of potassium is indicated in patients taking diuretics or undergoing bowel preparation; (3) a chest x-ray is indicated in patients with a history of cardiac or pulmonary disease or with recent respiratory symptoms; and (4) spirometry (forced vital capacity) is indicated in patients 40 years of age or older who have a history of cigarette smoking and are scheduled for an upper abdominal or thoracic procedure.

Table 3 American Society of Anesthesiologists' Physical Status Classification ⁵		
Classification	Description	Examples
Class I	Healthy patient with no systemic disorder	
Class II	Mild to moderate systemic disorder that need not be associated with the surgical problem	Chronic obstructive pulmonary disease Diet-controlled diabetes Extremes of age Medication-controlled hypertension Moderate obesity
Class III	Severe systemic disease that limits activity but is not incapacitating	Insulin-dependent diabetes Lifestyle-limiting pulmonary insufficiency Morbid obesity Stress-induced angina
Class IV	Incapacitating, life-threatening systemic disease	Active cardiac ischemia Advanced hepatic, pulmonary, or renal disease Refractory arrhythmia Signs of congestive heart failure Unstable angina
Class V	Moribund patient, not expected to survive 24 hours without an operation	Major cerebral trauma with increasing intracranial pressure Major trauma with shock Massive pulmonary embolus Ruptured aortic aneurysm with profound shock

testing is medically indicated as specifically dictated by the change in clinical condition.^{2,5,6,13}

A color-coded “at a glance” guide modeled on traffic signals (green = consensus to do a test; red = consensus not to do a test; amber = absence of consensus, “consider testing”) has been prepared to guide busy practitioners regarding when to order what preoperative test [see Figure 1]⁶; other similar guides abound [see Figure 2¹⁹ and Table 4]. Audits²⁰ of current preoperative laboratory testing practices will remain scrutinized by conscientious investigators, but professional guidelines consistently reveal persistent unnecessary preoperative testing.²¹

Changing Paradigms of Surgical Success

It is now clear that postoperative survival by itself is no longer an adequate assay of surgical success. Risk must be stratified before operation, and the degree of risk must be evaluated in light of both the quantity and the quality of postoperative life. Cost must then be judiciously assessed relative to a risk-stratified, quality-adjusted postoperative year of life. In 2008, Cohen and colleagues published an assessment of health economics.²² These authors calculated the cost-effectiveness ratio by dividing the incremental costs

ASA/Surgery	CXR	ECG	CBC	Lytes	BUN/Cr	Glucose	LFTs	PT/PTT	UA
ASA = 1	< 1 y/o	Red	Red	Red	Red	Red	Red	Red	Red

	> 80 y/o	Green	Green	Green	Green	Green	Yellow	Green	Green

Figure 1 Appropriate preoperative tests related to the patient's American Society of Anesthesiology (ASA) classification and age. *Red* indicates that the preponderance of evidence suggests that the test will not be useful (or positively influence patient care); *yellow* indicates that the test is controversial; *green* indicates that the test is useful. BUN = blood urea nitrogen; CBC = complete blood count; Cr = creatinine; CXR = chest x-ray; ECG = electrocardiogram; LFT = liver function test; PT = prothrombin time; PTT = partial thromboplastin time; UA = urinalysis; y/o = years old.

of surgical therapy by incremental benefits as quality-adjusted year of life (QALY), compared with standard medical care. They reported that cochlear implants for profoundly deaf children reduced lifetime aggregate costs and improved health; liver transplantation for primary sclerosing cholangitis cost \$41,000/QALY; implantation of cardioverter-defibrillators in patients with left ventricular dysfunction cost \$52,000/QALY, and surgery in 70-year-old men with a new diagnosis of prostate cancer increased costs and compromised health compared with watchful waiting.²² Thus, the purposes of this section are to add "dollar cost" and postoperative quality of life to the preoperative risk assessment equations. We also propose to describe the potential preoperative cardiac, pulmonary, and laboratory tests; analyze the significance of abnormal results; and ultimately develop a strategy for relating patient characteristics and the magnitude of the procedure to the menu of preoperative studies.

Although no one ever truly wants to undergo a surgical procedure, the results of surgery can be formidably gratifying to both patient and surgeon when the right operation is performed accurately, expeditiously, and for the right reasons, on the right patient at the right time. In attempting to bring about this state of affairs, surgeons must consciously and honestly balance the physiologic, psychological, social, and financial burdens of surgery against the anticipated benefits.²³ Although surgeons are not the only medical

professionals who must perform this kind of balancing act, we are the ones who do it most conspicuously.

Continuing refinement of the methods employed to stratify preoperative risks permits surgeons to "handicap" both patients and surgical procedures with greater precision. Outcome assessment must clearly incorporate the "sickness quotient," which is typically expressed in terms of the ratio of observed to expected outcome (O/E), into the assessment of therapeutic value. If a surgeon were to operate only on Olympic athletes with single-organ diseases (or no disease at all), his or her patients would likely do very well. Those of us who must operate on a more diverse patient population will have less gratifying results.

The most widely used risk classification system was developed by the ASA and is based on the patient's functional status and comorbid conditions (e.g., diabetes mellitus, peripheral vascular disease, renal dysfunction, and/or chronic pulmonary disease) [see Table 3].²⁴ The ASA index generally associates poorer overall health with increased postoperative complications, longer hospital stays, and higher mortality.

In addition to functional capacity and comorbid conditions, age is a robust determinant of operative risk, as is the type of operation. Vascular procedures and prolonged, complicated thoracic, abdominal, or head and neck procedures carry higher levels of risk. None of this is surprising.

ASA/Surgery		TESTS							Rx

Figure 2 Preoperative assessment strategies and recommended risk-reducing therapy relative to American Society of Anesthesiologists (ASA) classification performed by the surgeon and age. *Red* indicates that the preponderance of evidence suggests that the strategy or therapy will not be useful (or positively influence patient care); *yellow* indicates that it will be controversial; *green* indicates that it will be useful. Each discipline has its own quasibjective test for perceived patient fortitude. The anesthesiologists term it the ASA classification; surgeons use the frailty index or the “eyeball” test. Nutritionists refer to the subjective global assessment, whereas oncologists rely on Karnofsky scoring. In each instance, the subjective “eyeball” impression of a seasoned clinician has traditionally proven to be gratifyingly valuable. ECG = electrocardiogram; ETT = exercise tolerance testing; MUGA = multigated acquisition; PFT = pulmonary function test; y/o = years old.

WHAT TO LOOK FOR IN THE PATIENT’S HISTORY

We all deteriorate as we age. In fact, the Mayo Clinic uses age alone as the initial filter in its selection of preoperative tests for “healthy” patients. The anesthesiologists refine this ASA policy by defining the “health” of the patient [see Table 3], which requires a search for comorbid disease. The diseases and other indicators that seem to count most are those that reflect cardiovascular compromise: angina, a past myocardial infarction, and surrogates for coronary artery disease, such as diabetes, hypertension, obesity, and advanced age. Nothing else seems to have much effect. Goldman and colleagues first reported this observation in 1977.²⁵ They followed 1,001 patients through a major surgical procedure and related their preoperative history, physical findings, and routine laboratory work to major complications: perioperative myocardial infarction, cardiogenic pulmonary edema, ventricular tachycardia/fibrillation, and death. They then applied univariate analysis to ascribe varying numbers of points to each preoperative factor that predicted postoperative problems. *All of the ominous preoperative signals were those that reflected cardiovascular disease: recent myocardial infarction (10 points),*

congestive heart failure (11 points), any nonsinus cardiac rhythm (7 points), and advanced age (5 points). These cardiac risk factors were assigned high numbers of points, although, perhaps surprisingly, no other warning signs received more than three—not even carbon dioxide tension (Pco₂) greater than 50 mm Hg, BUN greater than 50 mg/dL, bicarbonate less than 20 mM/L, or potassium less than 3.0 mM/L. Liver function tests were so insensitive that they were deemed insignificant. In 1995, Mangano and Goldman repeated this study and reported the same conclusions.²⁶

Many risk stratification systems refer to “otherwise healthy patients.” The term “healthy patient” should be translated as “asymptomatic patient.” When you are taking the patient’s history, you should focus on probing for the indicators of cardiac disease.

INDICATORS OF CARDIAC RISK

In a successful attempt to simplify Goldman and colleagues’ equation, Boersma and colleagues refined the Lee and colleagues Revised Cardiac Risk Index (RCRI), which is currently the most widely applied cardiac risk stratification system.^{27,28} The RCRI identifies six predictors of major

Table 4 Preoperative Assessment Strategies Related to Purposes and Potential Information Derived

<i>Assessment Strategy</i>	<i>Information Derived</i>	<i>Purpose(s)</i>	<i>Indication/Comments</i>
Medical consultation	Assessment of chronic disease	To stabilize chronic disease	ASA classes III and IV (not typically useful in ASA I, II, or V)
Cardiac clearance	Assessment of chronic cardiac disease	To stabilize chronic cardiopulmonary disease	ASA classes III and IV (not typically useful in ASA I, II, or V)
Frailty (“eyeball”) test	Global assessment of surgical risk/benefit	Practical guide to surgical risk/benefit	Useful in assessing necessity/benefits of surgical intervention
Resting ECG	(1) Cardiac rhythm; (2) may reflect prior muscle damage (Q waves)	To determine resting cardiac rhythm	Disappointing indicator of cardiac status
Climbing 2–3 flights of stairs	Practical indicator of strength and cardiopulmonary status	Subjective indicator of cardiopulmonary status	Useful indicator of cardiopulmonary status in sorting out ASA class III patients
Exercise tolerance test	Quantitative indicator of cardiopulmonary status	Objective indicator of cardiopulmonary status	Useful if results might lead to cardiac intervention in the absence of proposed elective general surgery
Multigated acquisition (MUGA) scan	Ejection fraction	To assess ventricular function	Low yield in ASA class I, II, and III patients
Pulmonary function tests (PFTs)	Pulmonary status	To assess medical reversibility of lung dysfunction	Valuable in discriminating patients with equivocal 2–3 flights of stairs climbing test

ASA = American Society of Anesthesiologists; ECG = electrocardiogram.

cardiac complications (high risk surgical procedures, ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, insulin use and a creatinine greater than 2.0 mg/dL). Scores range from 0 to 5, and the likelihood of major perioperative complications increases with rising scores [see Table 5].^{25,26} This index has weaknesses. It was derived from calculations that excluded emergency surgical patients and neurosurgical patients, whereas thoracic, vascular, and orthopedic patients were overrepresented. In addition, it classified surgical procedures simplistically into two categories: high risk and non-high risk. Despite these weaknesses, the predictive accuracy of the RCRI has been validated in large cohorts.²⁷

Whereas the RCRI documents cardiac risk factors, the American College of Cardiology (ACC)/American Heart Association (AHA) Task Force guidelines (see below) were developed to serve as a national quality initiative for use of the RCRI and optimization of perioperative risk by medical or, rarely, surgical means. The goal of a preoperative cardiac consultation is to determine the most appropriate testing and treatment strategies for optimizing patient care while avoiding unnecessary testing. This represents a definite paradigm shift from the stratification and revascularization strategies commonly employed only a decade ago.

Interestingly, these guidelines are not always followed in clinical practice. One survey found that despite the availability of the guidelines, 40% of cardiology consultations resulted in the simple recommendation to proceed with surgery, without modification of perioperative plans or optimization of risk factors.²⁹ Patients selected for noninvasive testing do appear to receive more medical therapy (e.g., beta blockers, statins, and platelet inhibitors) than patients who are not referred for further cardiac evaluation.

ACC/AHA TASK FORCE GUIDELINES

Routine preoperative cardiac evaluation and testing suffer significant inherent limitations. The ACC and the AHA have

combined task forces to clarify current recommendations for national quality initiatives in perioperative stratification and risk modification.³⁰ Their strategy bases diagnostic and therapeutic approaches on clinical screening for disease state and functional capacity. Specialized testing is conservatively employed only when additional information provided by the proposed test is likely to impact the outcome. The ACC/AHA consensus guidelines recommend aggressive medical management to provide myocardial protection in the perioperative period to mitigate cardiac risk. This strategy has proven to be both efficient and cost-effective in vascular surgery patients. The most recent update of these guidelines was published in late 2007.³⁰

The ACC/AHA guidelines employ a five-step algorithm designed to guide patient risk stratification and subsequently determine appropriate cardiac evaluation. This algorithm is available on the ACC website (<http://www.acc.org/clinical/guidelines/perio/update/fig1.htm>).

Step 1 involves assessing the urgency of the operation. Step 2 is the process of looking for active cardiac conditions, including unstable coronary syndromes, decompensated heart failure, significant dysrhythmias, and severe valvular disease. If any of these conditions are present and the operation is elective, the patient should be evaluated further and treated according to ACC/AHA guidelines. Step 3 is activated when no active cardiac condition is present and the proposed operation is low risk. In this instance, the surgeon may proceed without further intervention. Step 4 includes operations that are deemed to be of intermediate to high risk. The patient's functional status must be determined [see Table 6]. If the patient is asymptomatic and functional status is good, the planned operation may proceed without further intervention. If the patient is symptomatic or functional status is undetermined or poor (defined as the inability to perform activities involving energy expenditure greater than 4 metabolic equivalents [METs]), further investigation is

Table 5 Revised Cardiac Risk Index²⁶

No. of Risk Factors	Risk of Major Cardiac Complications (%)
0	0.4
1	0.9
2	7.0
3+	11.0

There are six clinical risk factors: (1) high-risk surgery; (2) ischemic heart disease (myocardial infarction, positive treadmill test, use of nitroglycerin, current chest pain, pathologic Q waves on electrocardiogram); (3) congestive heart failure (documented history, pulmonary edema, paroxysmal nocturnal dyspnea, S₃ or chest x-ray with pulmonary vascular redistribution); (4) cerebrovascular disease (transient ischemic attack or cerebrovascular accident); (5) insulin-dependent diabetes mellitus; and (6) renal failure (progressive serum creatinine > 2.0 mg/dL).

necessary. In step 5, the final step, the surgeon searches for major clinical predictors of specific cardiac risk. As defined by the ACC/AHA Task Force, clinical cardiac risk factors include a history of ischemic heart disease, compensated or previous heart failure, cerebrovascular disease, diabetes mellitus, and/or renal insufficiency.³⁰ Patients with no history of clinical risk factors may proceed to surgery. Patients with one or two clinical risk factors who are undergoing a vascular procedure or patients with one or more clinical risk factors who are undergoing an intermediate-risk operation have the option of either proceeding with surgery after appropriate beta blockade or receiving additional evaluation,

but only if the results might change management. Patients with three or more clinical risk factors who are undergoing a vascular procedure should receive further evaluation, but, again, only if the results might change management.

Identification of Factors Affecting Cardiac Risk

Heart failure is the most common discharge diagnosis in hospitals across the United States. The prevalence of heart failure increases with age, and as our surgical population ages, we treat more and more elderly patients with relevant degrees of heart failure.

Numerous cardiac risk indices have been created over the past three decades. During that period, risk stratification has evolved from the early Goldman and colleagues criteria, the first substantial effort at risk assessment, to the RCRI developed by Lee and colleagues²⁷ [see Table 5]. A review of the initial and updated multivariate analysis of risk predictors prior to noncardiac surgery attributes the lion's share of risk to the cardiovascular system.^{25,26} If your patient suffers a major perioperative complication (myocardial infarction, cardiogenic pulmonary edema, sustained ventricular tachycardia/fibrillation, or death), the only organ system that appears to matter much is the heart.

To reiterate, Mangano and Goldman ascribe 11 points to any preoperative evidence of congestive heart failure, 10 points to a myocardial infarction within the last 6 months, 7 points to any ECG rhythm other than sinus rhythm, and

Table 6 Approximate Metabolic Equivalents and Peak Oxygen Intake Related to Common Daily Activities and Stages of the Bruce Protocol (Modified Duke Activity Status Index)

Activities: "Are you able to..."	Metabolic Equivalents (METs)	Peak Oxygen Intake* (mL/kg/min)	Bruce Protocol Correlates		
			Stage	% Grade	mph
Lie in bed with minimal movement (bedridden)?	≈ 1.00	< 10	NA [†]	NA [†]	NA [†]
Sit up in bed independently?	1.25				
Walk around the house?	1.75	10–15	1	10	1.7
Take care of yourself (toilet, feed, bathe, and clothe yourself?)	2.75				
Do light housework, such as washing dishes?	2.75				
Walk two blocks at ground level?	3.00	15–20			
Do moderate housework, such as vacuuming/sweeping floors?	3.50				
Do yard work, such as raking leaves?	4.50	20–25	2	12	2.5
Have sexual relations?	5.25				
Walk up a hill or climb two or three flights of stairs?	6.00				
Participate in moderate recreational activities such as swimming, golf, or slow dancing?	6.00	> 25	3	14	3.4
Do heavy housework such as lifting or moving heavy furniture?	8.00				
Run a short distance?	10.00		4	16	4.2
Participate in strenuous sports such as volleyball or basketball, run on a treadmill, or use an elliptical machine?	12.00				
Run a long distance?	12.00+				

NA = not applicable.

*Estimates of peak oxygen uptake are based on comparison data obtained from various levels of an exercise cardiac stress test (i.e., the Bruce protocol). These numbers vary by age and gender and hence represent estimates for women and men of differing ages.

[†]Bedridden patients are unable to participate in exercise stress testing. Hence, no data are available for this group in regard to Bruce protocol staging.

A physician may assess functional status as part of a preoperative checklist, but the patient usually provides only a snapshot of his or her most recent activities. Activity levels are not static but, rather, dynamic. Indeed, exercise tolerance can be gained over time with work ("training"). If patients are able to climb the ladder of activity status and tolerate more vigorous exercise, this is the ultimate cardiac stress test. Hence, increasing exercise in patients ("training") is a constructive preoperative formula.

5 points to age greater than 70 years of age (a surrogate for coronary disease).^{25,26} No other indices (including a PCO_2 greater than 50 mm Hg or a creatinine level greater than 3.0 mg/dL) warrant more than 3 points. So a seemingly innocuous sigmoid resection (abdominal surgery = 3 points) in a 70-year-old gentleman (5 points) in atrial fibrillation (7 points, and 20% of septuagenarians exhibit atrial fibrillation) who suffered just a “little” heart attack 3 months ago (10 points) climbs into the highest risk category with 26 total points. In the Goldman and colleagues and Mangano and Goldman studies, class IV risk (patients scoring more than 25 points) suffered a 26% chance of major complications such as ventricular tachycardia or ventricular fibrillation or death.^{25,26}

Now—15 to 30 years later—we may be doing a little better, but the cardiovascular system remains the culprit. The purposes of this section are to review the various tests of cardiovascular function and to develop a practical and safe algorithm for preoperative cardiac evaluation. There are no surprises here. The bigger the operation, the higher the cardiac risk; the older the patient, the riskier the outcome is likely to be. Conversely, even two decades ago, Warner and colleagues reviewed the 30-day mortality of over 45,000 patients undergoing outpatient anesthesia and surgery³¹ [see Figure 3]. Adjusting for age and gender, these authors concluded that the low-risk surgical procedure provoked no more deaths than would have occurred during a month without surgery. On the other hand, when a surgeon is confronted with a high-risk patient needing a high-risk procedure, a strategic alternative is not a retreat; it is responsible medicine. All too often, however, an elderly patient presents with a clear mesenteric vascular accident, and surgical intervention is the only option. This situation obligates a compassionate explanation to the patient, a sensitive discussion with the family, and a bold acceptance of reality by the surgeon. Most often, however, both the patient and the procedure are solidly positioned in an intermediate gray zone.

Conceptually, cardiac dysfunction may be comfortably discriminated into four broad categories. Each may be defined using standard cardiac function tests. These cardiac dysfunction categories are ventricular systolic compromise,

ventricular diastolic compromise, valvular heart disease, and myocardial ischemic disease resulting in electrophysiologic instability.

FUNCTIONAL CAPACITY

Patients who are able to exercise regularly without limitation generally have sufficient cardiovascular reserve to withstand stressful operations. Those with limited exercise capacity are prone to exhibit this poor cardiovascular reserve either during or after noncardiac surgery. Even outside the surgical arena, patients with poor functional status enjoy a shorter life span.³²

Functional capacity is readily expressed in terms of METs. One MET is equivalent to the energy expended (or the oxygen used) in sitting and reading this chapter (3.5 mL O_2 /kg/min). For a 70 kg person, one MET amounts to 70 kg $\times$ 3.5 mL O_2 /kg/min, or 245 mL O_2 /kg/min. Multiples of the baseline MET value can then be used to quantify the aerobic demands posed by specific activities. A modification of the Duke Activity Status Index³³ developed 20 years ago is still a practical guide [see Table 6].

Functional status correlates with exercise treadmill testing. Multiple studies have indicated that perioperative cardiac and long-term risks are increased in patients who are unable to meet the 4-MET demand associated with most normal daily activities. This higher-risk status can be signaled by poor performance on a treadmill test protocol [see Table 7]. However, just by talking with your patient, you can assess the patient's exercise capacity. This assessment is a practical, inexpensive, and accurate predictor of your patient's ability to tolerate a surgical stress.

RESTING ELECTROCARDIOGRAM

To determine whether a patient or an organ can tolerate a stress, we must stress that organ or patient. Intuitively, it does not make much sense to obtain a resting ECG in an asymptomatic young or middle-aged patient. With older patients, the resting ECG can exhibit abnormal rhythms and an old scar (big Q waves). In a retrospective analysis of 23,036 patients undergoing cardiac surgery, the preoperative ECG improved the predictive value of perioperative cardiac events in comparison with clinical risk stratification alone.³⁴ This predictive benefit was not apparent in low-risk patients undergoing low-risk procedures.³⁴ We conclude that a routine resting ECG prior to even major surgery in a young or middle-aged asymptomatic patient (ASA I/II) with no historical red flags is very low yield. Vascular disease, however, is systemic disease. Prior to vascular surgery, patients deserve a resting ECG.

Figure 3 A low-risk operation (such as a cataract) renders negligible additional morbidity and mortality to a patient (irrespective of American Society of Anesthesiologists [ASA] status) with or without the surgical procedure.

Table 7 Bruce Protocol Stress Test

Stage	% Grade	mph	METs
1	10	1.7	4.7
2	12	2.5	7.0
3	14	3.4	10.1
4	16	4.2	12.9
5	18	5.0	15.0

MET = metabolic equivalent.

Current guidelines discourage routine preoperative non-invasive cardiac testing for most intermediate-risk preoperative patients. In a 2006 study, 1,476 patients were stratified according to their RCRI scores.³⁵ Of these, 770 patients on beta-blocker therapy with tight heart rate control met the criteria for intermediate risk. This intermediate-risk group was split and randomly assigned to receive either cardiac stress testing or continued beta-blocker therapy. Some degree of ischemia was noted in 25.8% of the patients in the testing group, but analysis of the 30-day outcomes after operation found no difference between the two groups with respect to the incidence of major cardiac adverse events. The major difference was that patients in the untested group underwent their procedures 3 weeks sooner than patients in the tested group. Noninvasive cardiac testing even in intermediate-risk patients just takes additional time without discernible benefit.

In general, indications for specialized testing are the same prior to surgery as in the nonoperative setting. If your patient exhibits the kind of cardiac indicators that might warrant coronary revascularization in the absence of an impending surgical procedure, proceed with noninvasive testing; otherwise, do not proceed.

The timing of cardiac testing depends on the urgency of the noncardiac procedure, the risk factors present, and specific considerations associated with the procedure. Coronary revascularization before noncardiac surgery has sometimes been advocated as a way of enabling a patient to tolerate a noncardiac procedure, but it is appropriate only for a very small subset of very high-risk patients.

The ACC/AHA guidelines provide the following summary recommendations. In each instance, evidence is persuasive, or only Level B:

1. Pre- and postoperative resting 12-lead ECG is not indicated in asymptomatic patients undergoing low-risk surgical procedures.
2. Vascular disease is a systemic disease, so resting 12-lead ECG is indicated in patients undergoing vascular surgery.
3. Preoperative resting 12-lead ECG is recommended in patients with the following clinical risk factors: cerebrovascular disease, diabetes mellitus, renal insufficiency, a history of ischemic heart disease, or a history of congestive heart failure.

This leaves a relatively wide gray zone, in which there is only Level C, or “pretty good,” evidence:

1. Preoperative resting 12-lead ECG is not helpful in asymptomatic patients undergoing intermediate-risk surgical procedures.
2. Resting 12-lead ECG is recommended in patients with known coronary artery disease prior to intermediate-risk operations.

CARDIAC EXERCISE STRESS TESTING

A monitored exercise stress test would logically appear to be a safe way of reproducing the hemodynamic components of surgical stress. Exercise testing on a treadmill has the advantage that the results can be quantified in METs achieved, and the test (unlike an operation) can be rapidly aborted. The patient walks on a treadmill as the speed and

slope are increased [see Table 7]. Four outcome variables are continuously monitored: angina, ST-T wave changes, ectopy as a reflection of ischemia, and, most importantly, blood pressure. When a healthy person exercises, the blood pressure should rise. No change, or a decrease in blood pressure, is ominous both for perioperative cardiovascular complications and as a prognostic indicator of nonoperative life expectancy.³²

In 2009, the ACC collaborated with the AHA Task Force on Practice Guidelines and produced a comprehensive analysis of exercise stress testing for myocardial ischemia and functional capacity.³⁶ These authors provided a table cataloging 10 published studies in which high-risk patients prior to peripheral vascular or abdominal aortic aneurysm (high-risk) surgery were subjected to exercise stress testing preoperatively.

When exercise tolerance testing (ETT) is used to identify obstructive coronary disease, the results are disappointing. As many as half of the patients with a single 70% coronary artery stenosis will sail through ETT with a “normal” result. For patients with involvement of all three major coronary arteries or even left main disease, the sensitivity is better at 86%, the specificity remains only 53%.³⁷

The mechanics of an ETT are relatively straightforward. A 12-lead ECG is continuously monitored as the patient walks on a treadmill. The Bruce protocol is most commonly used [see Table 7]. The patient is required to walk at 1.7 mph (not very fast) on a 10% incline. Every 3 minutes, the incline is increased by 2%, and the treadmill speed is increased, as indicated below.

The patient is questioned continuously concerning chest pain and fatigue, while the blood pressure is determined at the end of each stage. Although the early stages of the Bruce protocol do not seem like a lot of exercise, this may need to be modified to a lower workload for sedentary and elderly patients. Thus, the first two stages of a “modified Bruce protocol” are conducted at 1.7 mph at a zero grade (stage I) and then a 5% grade (stage II).

The inconvenience and expense of formal exercise testing have prompted many investigations to develop more accessible and practical historical questioning and functional testing strategies. Therefore, the ACC and the AHA equate the ability to walk around the block on level ground as stage I (Bruce protocol) or less than 4 METs; walking up two flight of stairs is around 6 METs or stage II (Bruce protocol).³⁷

Nikolić and colleagues refined stair climbing by monitoring pulse oximetry in 101 patients prior to thoracic surgery as they climbed stairs.³⁸ Eighty-seven of the 101 patients suffered at least one postoperative complication. Disappointingly, age, gender, and oximetry-monitored stair climbing were not predictive. This is an example of high-risk patients undergoing high-risk surgery, so the experienced surgeon should have been prepared for trouble irrespective of any preoperative tests.

Conversely, multiple groups have linked the graded results of an ETT to a patient’s annual mortality.³² These investigators identified 12% of a medically treated group of patients with coronary artery disease who could manage only stage I of a Bruce protocol. These patients suffered over 5% annual mortality. In this study, 34% of patients carrying the diagnosis of coronary artery disease who could accomplish stage III of a Bruce protocol suffered less than 1%

annual mortality. It would appear to be a minor conceptual leap to assume that the risk characteristics predicting a short life are similar to the patient limitations that cause perioperative morbidity and mortality. For example, Myers and colleagues retrospectively studied the ETT results of 6,000 veterans (with and without a diagnosis of coronary artery disease) and compared the maximum METs achieved with annual medically treated mortality data.³² Again, patients who could achieve 8 METs or more suffered less than half of the mortality of patients who could not complete Bruce protocol stage I. The predictive value of METs in this study also overwhelmed smoking, hypertension, body mass index of 30 or greater, chronic obstructive pulmonary disease (COPD), and diabetes.³²

So functional capacity, measured in METs, is a comprehensive assessment of cardiopulmonary status and muscle strength and would appear to be superior to tests specific for myocardial ischemia in calibrating a patient's risk for perioperative morbidity and mortality.

VENTRICULAR FUNCTION TESTING

Radionuclide angiography, cardiac ventriculography, gated blood pool imaging, and multigated acquisition (MUGA) scans are different names for the same procedure. An intravenous injection of technetium-99m (pertechnetate) labels the patient's red blood cells (RBCs) in vivo. The patient's heart is then scanned with a gamma camera. Low-level gamma radiation is emitted by RBCs tagged with technetium, and the radiation detected at end-systole is then related to the radiation at end-diastole and thus permits calculation of an ejection fraction. The radiation emitted during a single cardiac cycle is not sufficient signal to reliably calculate the ventricular volumes, so multiple cycles are acquired "gated" to the ECG (thus, "multigated acquisition"). A healthy ventricle ejects about 60% of its end-diastolic volume with each heartbeat.

Exercise MUGA scanning can also be performed, typically with the patient on a stationary bicycle. With exercise, both the patient's blood pressure and ejection fraction should rise.

With advancing age and congestive failure, the increasing stiffness of the ventricles can be measured in terms of the time to peak filling rate. The shorter this interval, the more compliant the ventricle. Diastolic dysfunction is now increasingly recognized as an etiology of heart failure; the ventricle becomes too stiff to fill during diastole. A healthy heart should be capable of filling completely within 130 to 200 milliseconds.

In patients with a normal, healthy exercise capacity, preoperative measurement of ventricular function will be very low yield, and the possibility of modifying any perioperative strategy by virtue of this test is unlikely.

In addition to the obvious patients who present with congestive failure and/or limited functional capacity, the surgeon should be mindful of patients on chemotherapeutic drugs. Two common culprits are doxorubicin (Adriamycin) and immunotherapy (trastuzumab [Herceptin]), which are both frequently cardiotoxic.

STAIR CLIMBING: PUTTING IT ALL TOGETHER

Arguably, climbing stairs incorporates cardiopulmonary status, muscle strength, and "vitality" into a single practical

and inexpensive test of performance capacity. Brunelli and colleagues studied 640 patients scheduled for pulmonary resective surgery with a preoperative, symptom-limited stair climbing test.³⁹ Patients who climbed less than 12 m (less than two flights of stairs) experienced a twofold increase in complications ($p < .0001$) and a 13-fold increase in mortality ($p < .0001$) and incurred costs 2.5 times higher than patients who could manage a climb of 22 m (more than two flights). These investigators then refined the stair climbing test by concurrently measuring finger oximetry. While studying 536 patients breathing room air during stair climbing, they sought to determine whether oxygen saturation less than 90% or desaturation greater than 4% drop from resting level better discriminated the likelihood of postoperative complications. The stair climbing was uniquely suited to elicit oxygen desaturation, and patients exhibiting oxygen desaturation greater than 4% were twice as likely to suffer postoperative problems. Exercise-induced desaturation ($> 4\%$) appeared superior to resting finger oximetry as a predictor of postoperative problems.

Pulmonary Function Tests

Conceptually, pulmonary dysfunction may comfortably be divided into four broad categories: obstructive airway disease, hyperinflation, restriction, and diffusion (compromise). Each of these categories may be defined through the use of standard pulmonary function tests (PFTs).

OBSTRUCTIVE AIRWAY DISEASE

When surgeons receive multiple-page PFT results, we almost always focus first on a single parameter: forced expiratory volume in 1 second (FEV_1). This measurement requires patients to inhale to maximum lung volume (total lung capacity) and then exhale as forcefully and quickly as they are able to [see Figure 4]. These tests may require a "race correction" for ethnicity of as much as 6 to 12%. Healthy young adults can exhale almost all of their total lung capacity within a second or two, so a healthy FEV_1 approaches 4 to 5 L! After 2 seconds, healthy lungs have emptied down to residual volume. A patient with asthma or COPD cannot move air through airways that have been constricted by bronchospasm [see Figure 4]. So if your patient, following bronchodilators, can only exhale in 1 second (FEV_1) less than 70% of all they can inhale (forced vital capacity [FVC]), they have met the Global Initiative for Obstructive Lung Disease (GOLD) criterion for COPD ($FEV_1/FVC < 70\%$).

In a patient with significantly compromised airway resistance, pulmonary function should also be assessed following inhaled aerosolized bronchodilators. These drugs come in three varieties: short-acting β_2 agonists, such as albuterol; long-acting β_2 agonists, such as salmeterol; and methylxanthines, such as caffeine and theophylline.

Many receptor agonist/antagonist drugs are somewhat, but not absolutely, receptor specific. So in this chapter, when we recommend a β_2 agonist for perioperative bronchodilation and simultaneously encourage a cardio-specific β_1 inhibitor (such as metoprolol or atenolol) for cardio-protection, you may appropriately envision a patient entering the operating room with one foot capably placed on the accelerator while the other foot is simultaneously placed on the brakes.

Figure 4 A flow-volume loop relates volume of exhaled/inhaled gas to time (seconds). Note that the volume of air that a young, healthy person can forcibly exhale in 1 second (FEV_1) can be as high as 4 to 8 L. Chronic obstructive pulmonary disease (COPD) dramatically reduces air flow.

HYPERINFLATION

Lung volumes are measured using a relatively simple dilutional principle. For example, 1 L of 100% nondiffusible helium is added to a spirometer and mixed. When the helium concentration gauge reads 10% helium, the volume of the spirometer can be calculated to be 10 L. The respiratory technician then places a tube into the patient's mouth and connects the tube to the spirometer with a handheld valve. The patient is instructed either to achieve total lung capacity (TLC) and exhale down to residual volume (RV) or just to breathe comfortably, initiating each breath from functional residual capacity (FRC) [see Figure 5]. When the technician observes the patient to be at the desired lung volume, the technician flips the valve connecting the patient to the spirometer. The increased volume of dilution equals the patient's lung volume at the time the valve was opened. So if the valve is opened at the end of a comfortable tidal breath (FRC) and the helium gauge concentration falls to 8%, then the total volume of dilution must be 12.5 L (spirometer plus FRC volume), or 12.5 L minus 10 L (for the spirometer) equals a 2.5-liter FRC.

If the patient continues to breathe while connected to the spirometer, the helium concentration should stabilize at 8%.

We all sigh frequently. Try not to sigh for several minutes, and you will become surprisingly uncomfortable. When a young patient sighs, the helium concentration will remain at 8% (no increased volume of distribution). But when an elderly patient sighs, the helium concentration, which had previously leveled off at 7.5%, revealing a higher "hyperinflated" FRC of 3.33 L, typically falls a little further, perhaps

Figure 5 Spirometric lung volumes. The therapeutic purpose of positive end-expiratory pressure (PEEP) is to raise the functional residual capacity (FRC), or the lung volume following tidal exhalation, above closing volume so that terminal airways never close during tidal exhalation. RV = residual volume; TLC = total lung capacity; VC = vital capacity or the volume of the air exhaled from the TLC to RV.

to 7.35%. The sigh must have uncovered an additional volume of distribution or volume of previously trapped gas. The new total volume of helium distribution is now 13.61 L minus 10 L (spirometer) minus 3.33 L (FRC), and the volume of trapped gas is 280 mL. This volume of trapped gas cannot be due to atelectasis, because collapsed alveoli could not further dilute the helium concentration in the system. Therefore, this additional decrease in helium concentration must be due to previously trapped alveolar gas, producing perfused but not ventilated lung (shunt). Histologically, terminal airways have no cartilaginous rings to hold them open. With age, increasing interstitial lung water (which is characteristic of congestive heart failure), and obesity, these terminal airways collapse at lower lung volumes. The lung volume at which terminal airways collapse is termed "closing volume." Thus, a big barrel chest with a flat diaphragm, an increased anteroposterior diameter, and radiolucent lungs on a chest x-ray is a natural attempt by the patient to set the FRC above the closing volume. When the closing volume is above the FRC, terminal airways close during each tidal breath, creating a transient shunt.

Therapeutically, when we ventilate a patient, we can elevate FRC above closing volume by adding positive end-expiratory pressure (PEEP) [see Figure 5]. A decade ago, the Acute Respiratory Distress Syndrome Network (ARDSnet) reported that lower tidal volume ventilation (6 mL/kg) in patients with acute respiratory distress syndrome reduced mortality and increased ventilator-free days compared with traditional tidal volume ventilation (10 to 15 mL/kg).⁴⁰ Controversy lingers as to whether these lower tidal volumes promote further airway collapse.

RESTRICTIVE LUNG DISEASE

The ability to expand the lung can be constrained by chest wall scarring (secondary to a large burn), pleural fibrosis (secondary to tuberculosis), or a decrease in lung parenchymal compliance secondary to pulmonary interstitial fibrosis (multiple inflammatory etiologies).

Pulmonary function studies exhibit reduced lung volumes. The patient's vital capacity is reduced, but there is no obstruction to the airway flow, so the exhaled gas (the limited volume that there is) can be exhaled quickly. Therefore, the FEV₁/FVC ratio is normal or may actually be increased.

DIFFUSION COMPROMISE

Once oxygen arrives in an alveolus, it is uncommon for transfer across the alveolar-capillary membrane to be limited. One can imagine, however, circumstances in which this could occur. At extremely high pulmonary blood flow, blood might not linger in the pulmonary capillaries long enough to saturate hemoglobin. Conversely, with anemia, all available hemoglobin might be saturated very early as RBCs traverse the pulmonary capillaries. With hemorrhage into the lung parenchyma, oxygen can be diverted away from pulmonary capillaries. In late-stage emphysema, the alveolar septae are destroyed and the effective alveolar-capillary surface area is reduced, but this is not a diffusion problem. The classic pulmonary diffusion disease is an idiopathic interstitial pneumonitis (Hamman-Rich syndrome). Patients present with nonspecific shortness of breath. A lung biopsy reveals noncellular debris thickening the diffusion distance from alveolus to pulmonary capillary. The measured diffusion of carbon monoxide test (DLCO) should reveal compromised gas diffusion. Fortunately, true limitation of oxygen diffusion across the alveolar-capillary membrane is not common.

For a DLCO test, the patient inhales a tiny concentration of a maximally diffusible gas (carbon monoxide 0.3%) and a small volume of a maximally nondiffusible gas, such as helium, along with a large amount of room air. The patient holds his or her breath for 10 seconds and exhales. Concentrations of carbon monoxide and helium are then measured in the exhaled gas. Both gases will have been diluted by the inhaled breath, so the concentrations of both gases will decrease. Most of the diffusible carbon monoxide should have been transferred to the pulmonary capillary blood. The lower the exhaled carbon monoxide, the better the diffusion capability of the lung. Unfortunately, there are many ways to introduce error into this test. If the patient inhales rapidly, he or she can translocate additional blood into the pulmonary capillaries and falsely enhance the apparent diffusing capacity. Conversely, severe anemia permits rapid saturation of the limited hemoglobin with carbon monoxide, resulting in a false depression in the DLCO. A heavy smoker may live with carboxyhemoglobin as high as 10% and actually excrete carbon monoxide, thus confounding the test. Even most pulmonologists acknowledge that the DLCO is not a very good test.

Testing for Nutritional Abnormalities

For nutritional support, consensus statements and regulatory guidelines endorse the long-hallowed practice of identifying patients at increased risk for complications due to protein or calorie deficits. Again, this is called prognostic testing. The implication is that the benefit of special support will be confined to these patients. Poor functional status ("bedridden, requires assistance to ambulate") is a

bad prognostic sign [see Table 6]. In cancer patients, functional status is typically more important than nodal status, cytologic differentiation, or surgical margins in predicting morbidity and mortality. But assessing functional status provides no direct information on selection of therapy.

Much more therapeutically useful than prognostic testing is predictive (or directive) testing, which means identifying patients who will benefit from a specified, available intervention. By definition, predictive testing identifies that subset of "bad prognosis" patients who can be helped. This requires the existence of a therapeutic intervention of demonstrated benefit. It also requires the identification of those patients not too ill but not too well to benefit from the associated therapy.

Proof that a testing strategy is predictive or directive, not merely prognostic, is best demonstrated by randomized trials comparing outcome in groups receiving best conventional care with or without the proposed test. This is a high standard but has been met in some situations.

The therapy-prediction conundrum exists in nutritional support where possibly effective therapies have been applied in patients not able to benefit due to absence of an accurate predictive test to select the best target population. For example, identification of the role of vitamin B₁₂ in treating anemia awaited the ability to identify macrocytosis and, later, vitamin B₁₂ serum levels. Previously, most populations of anemic patients were dominated by those with iron deficiency, and no predictive test was available to find the subset benefiting from vitamin B₁₂ supplementation, so the benefit of vitamin B₁₂ remained unknown.

A vivid illustration of the difference between prognostic versus predictive/directive testing has recently arisen in breast cancer. The presence in breast tumor cells of human epidermal growth factor receptor type 2 (HER-2) has long been recognized as an indicator of poor prognosis, independent of stage, differentiation, or estrogen receptor status. Initially, nothing could be done in response to this information until the development of a blocker for HER-2, trastuzumab (Herceptin). Suddenly, HER-2 receptor testing permitted identification of a target patient capable of response. Patients with positive receptors given the blocker improved, whereas those with negative receptors did not. Not only was the HER-2 receptor test predictive, its prognostic implication also reversed itself. The receptor-positive patients now do better than average.

In nutrition for surgical patients, a variety of composite scores and indices have been proposed to predict prognosis. One clearly labeled prognostic measure, the Prognostic Nutritional Index (PNI), was proposed in 1980 to quantify surgical risk. This measure was used (in modified form) in the design of a large prospective, randomized trial of preoperative total parenteral nutrition (TPN) in veterans undergoing major general, vascular, or thoracic surgery.⁴¹ Patients judged too well nourished or too malnourished by this screen were omitted from the study, and the remainder, judged "moderately malnourished," were randomized into TPN or no TPN preoperatively. The modified PNI score was composed of albumin and weight loss scores only, which had previously been shown to be prognostic and easy to apply.

Unfortunately, after randomizing and treating 395 patients, the investigators found no outcome difference between the treatment groups, and in this sense, the trial's main result was negative.⁴² Retrospective subsetting by degree of severity within "moderate malnutrition" using a Subjective Global Assessment (SGA) tool⁴³ was then performed. This was interpreted to show that patients not severely enough malnourished to benefit from the extra protein and calories suffered increased septic complications and overall did worse with TPN. In contrast, the more malnourished patients did exhibit a net benefit.

For the studies reviewed in the following section, we use a scoring system that grades the conclusions as follows: Level A, supported by prospective, randomized, controlled trials (PRCTs) or meta-analyses of PRCTs; Level B, supported by nonrandomized, prospective, retrospective, or case-controlled studies; and Level C, supported by uncontrolled published experiences, case reports, or "expert opinion."

PREOPERATIVE TOTAL PARENTERAL NUTRITION

We have defined preoperative TPN to be intravenous provision of calories and nitrogen sufficient to meet metabolic needs for 5 or more days before elective surgery. Fourteen randomized, controlled trials of this approach, involving over 1,100 patients, have been examined,^{42,44-49} chiefly involving gastrointestinal cancer patients with at least moderate malnutrition and typically providing at least 7 to 10 days of preoperative TPN. Ten of these 14 studies found a benefit from TPN, which in five reached conventional statistical significance for reduced postoperative morbidity. The pooled results indicate an overall reduction in the risk of postoperative morbidity of about 10% in the TPN groups, that is, a reduction in the rate of complications of approximately 30%. Only one center found a statistically significant reduction in mortality [see Figure 6].

Based on these studies, we conclude that for malnourished gastrointestinal cancer patients, 7 to 10 days of preoperative TPN reduces postoperative morbidity (Level A).

POSTOPERATIVE TOTAL PARENTERAL NUTRITION

Routine administration of TPN to general surgical patients in the immediate postoperative period has been studied in nine randomized, controlled trials involving over 700 patients.^{46,50-54} No consistent benefit has been demonstrated, and the possibility of harm has been raised. These data are summarized in Figure 7.

Based on these studies, we conclude that, outside of a study situation in defined patient groups, routine use of postoperative TPN is not recommended (Level A).

It is also clear that nutritional support of patients unable to eat for long periods after surgery is needed to prevent starvation. The duration of starvation that can be tolerated without increased morbidity is unknown and depends in part on the previous nutritional status and current metabolic stresses the patient faces. Most feel that, after 5 to 10 days without adequate intake, special support is appropriate (Level C). For stressed or already malnourished patients, this interval will be shorter. Although the enteral route of administration is preferable, if the gut is not working adequately, TPN is needed (Level B).

Figure 6 Effect of preoperative total parenteral nutrition on postoperative complications.¹⁰¹

In the majority of trials summarized here, the quantity and type of substrates given were not what is now thought to be optimal. For example, calories were often given in amounts substantially greater than metabolic needs. It is

Figure 7 Effect of early postoperative total parenteral nutrition (TPN) on postoperative complications. These results are disappointing, but the quantity and type of substrates infused in these trials were not what is now thought to be optimal.¹⁰¹

probable that outcomes in many of these trials would improve if the trials were repeated using present-day understanding of caloric needs and other metabolic requirements in specific patient groups (Level C).

SPECIAL ENTERAL FEEDING

Provision of special enteral nutrition via tubes placed in the gastrointestinal tract perioperatively has been studied in 10 randomized trials.^{55–57} Five of these compared the enterally supported to patients receiving TPN, and the other five used a comparison group of routine oral feeding. In the enteral nutrition versus TPN trials for postoperative trauma patients, septic morbidity and mortality were minimized with enteral feeding, which is deemed superior to TPN.

One study reported a decrease in mortality in burned children provided with high-protein enteral supplementation compared with standard feeding.⁵⁶ A trial of nocturnal tube feeding in malnourished female hip fracture patients demonstrated speedier rehabilitation and shorter hospital stays.⁵⁷

On the basis of the available information, we conclude that special enteral nutrition is helpful in burn and malnourished hip fracture patients (Level A). In trauma patients requiring special support, the enteral route is associated with decreased septic morbidity compared with the parenteral route (Level A).

TIGHT GLUCOSE CONTROL

Extending work from the world of chronic diabetes management, in which ever-tighter glucose regulation is associated with improved outcomes, **Van den Berghe and colleagues presented two large randomized trials on intensive care (ICU) patients receiving supplemental calories early in their courses.^{58,59} The first of these, on surgical patients (chiefly postoperative cardiac patients), revealed a clear benefit in morbidity—and a raw reduction in mortality of 11%—when glucose levels were maintained below 110 mg/dL. Hypoglycemia in this ICU setting was not a serious problem.⁵⁸ A follow-up study from the same authors showed little or no benefit using the same approach in medical ICU patients.⁵⁹ Finally, a large (over 6,000 patients) multinational study coordinated from Australia and New Zealand found a worsening of mortality with tight glucose control in similar patients.⁶⁰**

The issue of tight control is of obvious importance in TPN patients, and it may be that disappointing results in the perioperative trials summarized above might be improved with better glucose regulation. Tighter glucose control carries risks of hypoglycemia and hypokalemia.³⁶

Target glucose levels in recent randomized trials appear to be converging toward about 140 to 150 mg/dL. Until more definitive data are available, this target seems safe for patients treated outside an ICU (Level C).

IMMUNONUTRITION AND “DESIGNER FEEDS”

The provision of special nutrients with the intent of stimulating the immune system, or providing targeted support for a failing liver or kidneys, and thereby reducing septic complications has been studied in a large number of trials that were reviewed by Dhaliwal and Heyland,⁶¹ with variable results. A fundamental problem is the use of ad hoc

mixtures of arginine, fish oil, RNA fragments, and sometimes glutamine, in various proportions, for which no rationale is given. The more recent of these trials have been much less encouraging than the earlier reports, with actual harm being reported in several trials of products containing high arginine levels. The recent publication from Holland of a randomized blinded trial of nearly 600 patients testing this strategy is unequivocally negative and may serve to foster a more cautious scientific approach toward evaluating such strategies.⁶²

Immunonutrition and “designer” feeds are not supported by a satisfactory evidence base (Level C).

PREOPERATIVE ORAL CARBOHYDRATE LOADING

The traditional dictum of nihil per os (NPO) after midnight for procedures to be performed under general anesthesia has been challenged in some centers in Scandinavia and eastern Europe since the 1990s. In these facilities, anesthesiologists provide several hundred milliliters of carbohydrate-enriched electrolyte solutions swallowed 2 hours prior to surgery. The rationale is that stress-induced insulin resistance is normalized and patient well-being improved by ingestion of these “potions.”⁶³ Interestingly, similar biochemical changes are also produced by glucose-containing intravenous lines in fasting preoperative patients.⁶⁴

Ingestion of 200 mL clear liquids does not increase the risk of aspiration pneumonia as long as there is a delay of 1.5 to 2 hours before anesthesia. A Cochrane Review first published in 2003 concludes that no strong evidence of harm from this practice can be adduced.⁶⁵ The generally small sample size in these reports contributes to this conservatism; most reports include fewer than 50 patients per group and are thus not powered to detect rare but catastrophic events. Gastric fluid secretion is traditionally quantified at approximately 100 mL/hr, so the gastric volumes are not likely to be influenced measurably by this preoperative cocktail.

Those concerned about insulin resistance might more easily and conventionally start the usual intravenous line an hour or two earlier and administer glucose by that route. But wetting the patient’s thirsty tongue with 200 mL of clear fluid 2 hours prior to surgery is very likely to enhance patient comfort at negligible risk of aspiration (Level B).

How Can We Make Surgery Safer?

The problem with searching the available, conscientiously conducted clinical trials for answers is that the patients recruited for those trials never really fit the patient you are currently considering for surgical therapy. As indicated above [see Figure 3], patients undergoing “low-risk” operations will do pretty well even if they present with significant comorbidities—or as well as they would do without surgery.³¹ The risk stratification strategies^{25,26} [see Table 3 and Table 5²⁷] each target the patient’s cardiovascular system as the overwhelmingly dominant culprit promoting perioperative trouble.

Over the past decades, the scope of perioperative efforts to reduce cardiac risk with cardioprotective therapy has changed. At present, the emphasis is on plaque stabilization, reduction of myocardial oxygen demand (reduction of oxygen delivery to oxygen consumption mismatch), and

myocardial protection, with revascularization reserved for a discrete subset of patients who would be candidates for cardiac revascularization regardless of any elective preoperative evaluation. It is hypothesized that the likelihood of coronary artery plaque rupture may be increased by perioperative stressors such as amplified sympathetic activation, vasospasm, disruption of coagulation homeostasis, and oxygen supply-demand mismatch.⁶⁶

Physicians, and perhaps more clearly surgeons, are sufficiently intellectually arrogant that we are more comfortable accepting a conclusion if we can understand the “mechanism” of the recommendation. Thus, if the heart is the organ that most endangers our patients, and we can reduce cardiac work/stress with a beta blocker, why not give this perioperative, antiadrenergic protection to all of our patients—or at least to all surgical patients with cardiovascular disease? Interestingly, and perhaps predictably, perioperative beta blockade produced a significant reduction in mortality in patients undergoing abdominal aortic aneurysmectomy (most likely patients with concurrent coronary artery disease).⁶⁷ No such benefit was appreciated in patients who were less likely to suffer comorbid coronary artery disease undergoing esophagectomy, hepatectomy, pancreatectomy, colectomy, gastrectomy, or pulmonary lobectomy.⁶⁷ These investigators concluded that evidence-based process measures are “procedure specific” and do not necessarily reflect overall hospital quality.

If some patients do not appear to benefit from perioperative beta blockade, is overuse of this particular therapy likely to hurt them? Some controversy remains regarding appropriate management of patients identified preoperatively as having significant but stable coronary artery disease. Current data support the use of presumptive medical therapy, and this has led to reductions in the extent of preoperative cardiac assessment, thereby decreasing the time from surgical diagnosis to surgical therapy. Perhaps surprisingly, documented coronary stenoses account for only 50% of perioperative myocardial infarctions; the remaining 50% occur in vascular distributions unrelated to documented coronary disease.^{68,69} The presence of severe stenosis is more a “marker” of disease, and thus the subset of patients at risk, rather than a finite predictor of endangered myocardial territory. In part, preoperative cardiac testing identifies this “at-risk” subset, even though the stenotic lesion may not be the cause of the postoperative ischemic event. The inability to assess the propensity for coronary plaque rupture proves to be the main challenge in both risk stratification and risk factor modification.

THE BETA-BLOCKER CONTROVERSY

The purported advantages of beta-blocker therapy include prolongation of diastole (and, thus, augmentation of diastolic filling with concurrent accompanying improvement in coronary artery perfusion), reduction of ischemic ventricular dysrhythmias, and reduction of sympathetic tone.^{70,71} Despite the plethora of available data, the argument for preoperative use of beta blockers to modify cardiac risk remains controversial. Except in high-risk vascular procedures, perioperative cardiac events are so rare among patients enrolled in randomized, controlled trials of perioperative beta blockade that any absolute reduction in cardiac risk is difficult

to detect. However, in high-risk vascular procedures, the data are overwhelmingly persuasive. Poldermans and colleagues screened 1,351 vascular patients (high risk) and identified 846 patients with one or more cardiac risk factors (very high risk).⁷² Of this group, 173 patients exhibited positive dobutamine stress echocardiography (very, very high risk). Fifty-nine patients were randomly assigned to perioperative beta blockade and were compared with 53 patients who received “standard” perioperative care. The primary end point of death or nonfatal myocardial infarction occurred in two (3.4%) of the beta-blocker group and in 18 (34%) of the standard care group (3.4% versus 34%; $p < .001$). It is clearly not permissible to extrapolate from this “very, very high risk” procedure-specific group to a “routine” general surgical patient.

Unfortunately, the studies on the opposite end of the risk spectrum are more confusing. Lindenauer and colleagues divided 782,969 patients (a huge number) into high, intermediate, and low risk for major, noncardiac surgery.⁷³ Again, perioperative beta blockade was associated with reduced risk for in-hospital death in high-risk patients. Perhaps surprisingly, beta blockade appeared to provoke increased trouble in the low-risk group. Subsequent review of this study design suggested that the low-risk patients did not receive beta blockers preoperatively and did not enter the beta-blocker arm of the study until after their operation, at a time when they were treated for a postoperative cardiac event.

The POISE Study Group attempted to resolve any recommendation to liberalize the use of beta blockers in noncardiac surgery by prospectively randomizing 8,351 patients at 190 hospitals in 23 countries.⁷⁴ The frighteningly formidable logistics of this study obligated a simplified investigative strategy. A large dose (two to eight times the standard dose) of extended-release metoprolol was given 2 to 4 hours before surgery to 4,174 patients unless their heart rate was below 60 beats/min. Fewer patients in the metoprolol group (5.8%) than in the placebo group (6.9%) reached the primary end point ($p < .0399$), but more patients in the beta-blocker group suffered a stroke (1.0% versus 0.5%) and/or died (3.1% versus 2.3%). In commentary on the POISE study, the 2009 ACC/AHA consensus document endorsed the use of beta blockers in high-risk patients but cautioned that: “routine administration of higher dose long-acting metoprolol in beta-blocker naïve patients on the day of surgery and in the absence of dose titration is associated with an increase in mortality.”⁷⁵ Clinical investigation is hard to do. To enhance patient recruitment and standardize the POISE experimental protocol, patients with a heart rate over 60 beats/min were given a large dose of an extended-release beta blocker. In high-risk patients, even this regimen provided protection. However, neither we, nor they, should be surprised that a large dose of beta blocker to a patient with a heart rate of 60 beats/min might provoke bradycardia and hypotension with a resultant increase in cerebrovascular accident and even death.

Multiple smaller studies examining noncardiac surgical patients with surrogates for coronary artery disease such as diabetes,⁷⁶ mild hypertension,⁷⁷ and advanced age⁷⁸ have typically reported fewer instances of perioperative myocardial ischemia in the beta-blocker group but were not sufficiently powered to detect more ominous outcomes.

To date, the issues of how, when, how long, titration limits and by whom beta blockers should be used in noncardiac surgical patients remain controversial. A conservative series of recommendations might include the following:

1. When preoperative beta-blocker therapy is used, it is optimally initiated 1 to 2 weeks prior to surgery, targeting a resting heart rate of 60 to 80 beats/min and monitored to avoid hypotension (Level A).
2. Although it is not permissible to extrapolate from patients following a myocardial infarction to patients during noncardiac surgery, Cucherat assembled 17 trials of beta blockers in post-myocardial infarction patients and estimated that each reduction in heart rate of 10 beats/min (in the absence of hypotension) accrued a relative reduction in cardiac death of 30% (Level A).⁷⁹
3. When a patient presents already on beta blockers, do not stop them (Level A).
4. The higher the perceived risk of the (especially vascular surgical) patient, the more likely it is that beta blockers will help (Level A).
5. Untitrated large doses of extended-release beta blockers in drug-naïve, low-risk patients are contraindicated (Level A).
6. This leaves a large middle “gray zone” group of patients in whom surgeons are on their own to use their best judgment.

STATINS

The statin (HMG-CoA [3-hydroxy-3-methylglutaryl coenzyme A] reductase inhibitor) story is complex but becoming clearer. HMG-CoA reductase is the rate-limiting step in cholesterol synthesis. Statins both inhibit cholesterol synthesis and increase expression of low-density lipoprotein (LDL) receptors, which results in an increased clearance of circulating LDL cholesterol. Cholesterol is, however, critically important to cell membrane stabilization. Cholesterol is the glue that holds the functionally important cell membrane phospholipids together. Only 20% of our cholesterol is ingested, whereas over 75% is synthesized by the liver. So, intuitively, it should be dangerous to manipulate this structurally pivotal molecule. Over 40 years ago, the Framingham study first associated hypercholesterolemia with atherosclerotic cardiovascular disease. So it made sense to try judiciously to lower cholesterol a little. A storm of inquiry followed. Law and colleagues recently reviewed several hundred trials and concluded that a reduction of LDL cholesterol by only 1.8 mmol/L conveyed a 60% decrease in ischemic heart disease and a 17% decrease in stroke.⁸⁰ Statins not only prevent heart disease; Poynter and colleagues reported a 47% reduction in the relative risk of colorectal cancer after adjusting for other recognized risk factors.⁸¹ If both atherosclerosis and malignant neoplastic degeneration are exacerbated by systemic inflammation, then statins might be effective in pacifying inflamed patients (as evidenced by an elevated C-reactive protein) even independent of absolute LDL levels. And, Albert and colleagues report that they are.⁸²

Surgery provokes inflammation. Logically, statins should help. Pan and colleagues and Ouattara and colleagues both reported a significant dose-dependent reduction in adverse cardiovascular outcomes with statins in coronary artery

bypass surgery.^{83,84} Biccard examined the implications of comorbid disease associated with perioperative cardiovascular risk for patients on statin therapy, the indications for perioperative statin protection, and the efficacy of acute perioperative beta blockade in addition to statin therapy and the effect of perioperative statin withdrawal.⁸⁵ Although many of the recent recommendations regarding retrospective reporting of statin trials may minimize some inherent investigator bias, the benefit of perioperative statins appears secure. Statins seem to benefit surgical patients with both cardiovascular and neoplastic disease; age overwhelms both of these indications. **Patients who benefit from perioperative beta blockers are the same group that will likely derive advantage from statins.** The data here are fuzzier, but in high-risk patients, both beta blockers and statins are useful. The dose and duration of preoperative prophylaxis are not clear, but 2 weeks is better than 2 hours. When a patient is already taking a statin, do not stop it.⁸⁵

Smoking Cessation Programs

It is hard to stop smoking; it is an addiction. Although there is a paucity of data indicating that smoking cessation just prior to surgery changes outcome, there are a lot of data linking smoking to perioperative trouble. So, intuitively, it makes sense to ask your patients to stop. A planned surgical procedure, especially if the purpose is to resect cancer, can provide persuasive incentive. Cooley and colleagues recommended smoking cessation to patients undergoing surgery for lung cancer.⁸⁶ Eighty-four patients (89%) were “ever-smokers,” and 35 (37%) reported smoking at diagnosis. Forty-six percent of the ever-smokers remained abstinent, 16% continued smoking, and 38% relapsed. In a separate analysis of lung cancer patients, these investigators catalogued the factors associated with failure to stop as young age, depression, and a household member who smokes.⁸⁷ A similar study identified the red flags of smoking cessation failure as mentholated cigarettes and a habit of enjoying the first cigarette within 30 minutes of awakening in the morning.⁸⁸

Several groups have tested smoking cessation programs in a prospective, randomized fashion.^{89,90} Prior to elective surgery, 210 smokers were randomly allocated to a nicotine replacement group or a “usual care” group. A whopping 73% of dependent smokers (> 10 cigarettes/day) reported (no confirmatory tests) abstinence prior to surgery compared with 56% abstinence in the “usual care” group. The bad news, however, is that 3 months following surgery, 82% and 95% of patients, respectively, were smoking again.⁸⁹

A single puff on a cigarette produces profound vasoconstriction. Some surgical groups believe that it is justified to refuse breast reconstructive surgery to smokers.⁹¹ Although it is clear that smokers suffer more postoperative complications, it is not evident that these problems will vanish if they stop.

The news is not all bad, however. Varenicline is a partial agonist/antagonist selective for $\alpha_4\beta_2$ nicotinic acetylcholine receptors that is touted as a first-line treatment smoking cessation option. Garrison and Dugan reviewed eight clinical trials and reported continuous abstinence rates ranging from 21.9 to 34.6% at a year.⁹² In a very slow race, even the lame can win.

Frailty Index: The “Eyeball” Test

Age is not the distance from the beginning but, more accurately, the proximity to the end. Although “frailty” has not yet achieved a standardized definition, we all recognize the status when we see it. Age and frailty are frequent, but not obligatory, partners. Frailty confers an increased risk of disability, falls, cognitive decline, hospitalization, and perioperative morbidity/mortality. Interestingly, the phenotype of frailty is not concordant with either disability or comorbidity, but the pathogenesis of frailty includes comorbidities, and disability is more the outcome than the cause.

Frailty can now be diagnosed as a medical syndrome.⁹³ Fried and colleagues identified this entity with three or more of the following: (1) unintentional weight loss of more than 10 pounds over a year; (2) self-reported exhaustion; (3) weak grip strength; and (4) slow walking speed or low physical activity [see Figure 4].⁹⁴ In this study, frailty was independently (stratifying for comorbidities) predictive (over 3 years) of falls, declining mobility, hospitalization (and intuitively perioperative morbidity/mortality), and death, with hazard ratios ranging from 1.82 to 4.46. Socioeconomic status resurfaces again, with frailty associated with lower education and income. As more statistics are successfully dissociating frailty from age,^{95,96} frailty has now been proposed as the missing element in predicting operative mortality.⁹⁷

Makary and colleagues prospectively measured frailty in 594 patients older than 65 years.⁹⁸ They used a 5-point scale, including weight loss, weakness, exhaustion, low physical activity, and walking speed. Frailty independently predicted postoperative complications, length of hospital stay, and nursing home discharge. Frailty even enhanced the predictive power of the ASA risk index ($p < .01$).

Although both the ASA and frailty indices aspire to quantitative status, the predictive (albeit subjective) value of the “eyeball” test performed by an experienced surgeon remains invaluable (although not formally tested). We continue to endorse this test.

An exercise prescription as an antidote to frailty^{99,100} would make intuitive sense in the preoperative period. Castillo-Garzón and colleagues provided compelling evidence that patient-specific exercise programs can attenuate the negative consequences of frailty.¹⁰⁰

7 ELEMENTS OF COST-EFFECTIVE NONEMERGENT SURGICAL CARE

Robert S. Rhodes, MD, FACS, Charles L. Rice, MD, FACS, and Julie Ann Sosa, MA, MD, FACS

Citizens of industrialized nations generally enjoy a high level of health, and the positive correlation between life expectancy and per capita income is among the best known relationships in international development.¹ Yet there are differences among the health care systems of these nations with regard to quality, cost, and access to care.^{2,3} There also appears to be a dynamic tension among these three characteristics, and the goal of providing broad access to high-quality health care at a reasonable cost is an increasing challenge. One particular challenge is that health care costs tend to rise at a faster pace than the costs of other goods and services. In the United States, for example, health care costs have consistently risen faster than overall inflation for the past 65 years. Interestingly, despite differences in the percentage of gross domestic product (GDP) that nations spend on health care, the slopes of these curves often appear to increase in parallel [see Figure 1].

The hyperinflation in health care costs, particularly in the context of the recent economic downturn, often forces choices among social goals (e.g., health care versus education). Such choices may be more readily rationalized when the costs of the chosen goal produce demonstrable value (i.e., if greater health care spending generates measurably better health, it is regarded as worthwhile; if it does not, it is regarded as wasteful). Unfortunately, the latter appears to be the case in the United States. Although the United States spends more on

health care as a percentage of its GDP [see Figure 1] and per capita [see Figure 2] than other industrialized nations, its citizens seem less healthy than those of many nations with respect to indices of population health, such as life expectancy and infant mortality [see Figure 3 and Figure 4]. Thus, per capita health care expenditures have only a modest correlation with life expectancy. Although some of this disparity in the apparent value of health care might be explained by specific characteristics of the US population, much of it cannot. Although the United States has slight advantages over some countries in 5-year survival rates for both breast and colorectal cancer, the cost of such benefits seems disproportionately large. Overall, the United States lags behind other nations in measures of illness and some chronic conditions amenable to health care.⁴ All of this suggests that the US health care system exhibits a relative lack of cost-effectiveness, the causes of which include higher prices for health care goods and services⁵ and waste related to overuse or misuse of resources.

As health care increasingly competes with other social goals for the same funds, individuals, employers, and governments all feel the strain. The impact on US citizens is reflected in the fact that in 2007, over 62% of personal bankruptcies were related to health care issues, up from 46% 6 years earlier.⁶ Also, the percentage of nonelderly Americans who lived in

Figure 1 Health care spending as a percentage of gross domestic product (GDP) among selected countries within the Organisation for Economic Co-operation and Development (OECD). US health care spending has been increasing at a disproportionately faster rate. Note that the x-axis scale does not have constant intervals. (www.oecd.org/health/hcqi, accessed July 5, 2010).

Figure 2 Health care spending per capita among selected countries within the Organisation for Economic Co-operation and Development (OECD) in US dollars. Again, US health care spending is increasing at a disproportionately faster rate. Note that the x-axis scale does not have constant intervals. (www.oecd.org/health/hcqi. accessed July 5, 2010).

Figure 3 Life expectancy among selected countries within the Organisation for Economic Co-operation and Development (OECD). The increase in US life expectancy is falling behind the increases seen in other countries. Note that the x-axis scale does not have constant intervals. (www.oecd.org/health/hcqi. accessed July 5, 2010).

families spending more than 10% of their income on health care rose from 14.4% in 2001 to 19.1% in 2006.⁷

The phrase “bending the cost curve” refers to efforts to minimize or eliminate differences in inflation in general and inflation in the cost of health care. Accordingly, there is a long history of attempts to control health care costs that includes price controls (the Nixon era), prospective payment (the Reagan era), and managed care (the Clinton era). Unfortunately, these initiatives had little long-term impact.⁸ More recently, concerns about increases in health care costs were sufficient to engender federal legislation aimed at controlling costs; whether this effort will be more successful has yet to be determined.

Many factors contribute to the costs of health care, but physicians’ decisions are the largest single factor; they are estimated to account for 75% of these costs. This pronounced impact of physicians on health care costs explains, in turn, why those who pay the bills increasingly seek to identify the most cost-effective physicians. Surgeons in particular are likely to be a target of efforts to contain costs because surgical illnesses often are of relatively short duration, surgical outcomes are readily quantified, and surgeon reimbursement often involves global fees.

Given the impetus to improve the cost-effectiveness of surgical care, the goals of this chapter are to (1) explore the fundamental principles of cost-effectiveness, particularly as

Figure 4 Infant mortality per 1,000 live births among selected countries in the Organisation for Economic Co-operation and Development (OECD). The decline in US infant mortality is not keeping pace with the declines seen in other countries. Note that the x-axis scale does not have constant intervals. (www.oecd.org/health/hcqi, accessed July 5, 2010).

applied to surgical care; (2) review the attributes and complexities of both cost and quality; (3) review current data on the relationship of cost and quality; and (4) identify specific skills and attributes to help surgeons deliver more cost-effective care.

Fundamental Principles of Cost-effectiveness

Cost-effectiveness expresses the cost of a given strategy (in dollars) relative to a given measure of quality. Developed in the military and in the evaluation of how to spend government monies on different public works projects (e.g., roads, dams, bridges), cost-effectiveness analysis (CEA) was first applied to health care in the mid-1960s. It was introduced with enthusiasm to clinicians in 1977 by Weinstein and Stason⁹ but was received with skepticism or reluctance. Cost-effectiveness can be an absolute term, but a more frequent application in health care is to compare the value of two or more clinical strategies. Expressed mathematically, it is the difference in the cost of a new strategy and the cost of current practice divided by the difference in the effectiveness of the new strategy and the effectiveness of current practice. Specific strategies might include assessing one intervention against another, assessing an intervention against no intervention, or assessing early treatment against delayed treatment. An example of the last is a study of appendicitis that concluded that each 10% increase in diagnostic accuracy was associated with a 14% increase in the perforation rate; the greater costs associated with higher morbidity from perforation might offset the cost savings associated with reducing negative appendectomies through greater diagnostic accuracy.¹⁰

Cost-effectiveness differs from cost-benefit, which measures return on investment (where the numerator and denominator are expressed in dollars), and from efficiency, which is an expression of productivity (with outputs divided by inputs).

Comparative effectiveness is another frequently used term that compares the effectiveness of two or more treatments.

Given that cost-effectiveness considers both cost and quality, changes in cost-effectiveness also represent changes in the value of care. The interaction of cost and quality also means that improvements in cost-effectiveness can result from changes in the numerator, the denominator, or both. Moreover, beneficial effects in one component of a strategy can be outweighed by adverse changes in the other, and vice versa. These interactions are represented in Figure 5. Here, strategies that increase quality and lower cost are highly desirable, and maximal cost-effectiveness is the optimal outcome that can be achieved with the least use of resources. Conversely, changes that lower quality and increase cost are clearly undesirable. In contrast, judgments of strategies where costs and quality move in the same direction tend to be controversial.

The controversial nature of such changes was evident during the debate on health care reform. Greater support for cost-effectiveness research was included in the American Reinvestment and Recovery Act (ARRA) of 2009, raising concerns that health care decisions going forward might be made by outside agencies. This fueled at least some of the opposition to health care reform.¹¹ Moreover, a recent survey indicated that a majority of consumers believed that more care meant higher-quality, better care.¹² Many of these consumer beliefs, values, and knowledge are at odds with what policy makers described as evidence-based health care. These beliefs likely account for the recent pushback on the changes in recommendations proposed by the U.S. Preventive Services Task Force regarding the appropriateness of routine mammography screening for women ages 40 to 49.¹³

Attributes of Health Care Costs

Assessing cost-effectiveness may seem simple, but measures of costs have multiple dimensions that are reflected in the phrase “cost is a noun that never stands alone.” Thus,

Figure 5 Cost analysis methods. Adapted from the National Information Center on Health Services Research and Health Care technology of the US National Library of Medicine, National Institutes of Health. Available at: <http://www.nlm.nih.gov/nichsr/hta101/ta10106.html>. accessed January 10, 2011. CEA = cost-effectiveness analysis.

assessing the relative cost-effectiveness of a specific strategy requires a precise definition of the costs being considered.¹⁴

An important first step is to appreciate the distinction between costs and charges. Charges are the price at which a “seller” provides a given product or service, but this price may not reflect the actual cost of that product or service (e.g., a loss leader). Although aggregate hospital costs can be a relatively constant fraction of hospital charges, there are often substantial variations among institutions in the cost-to-charge ratio for specific goods and services. These differences can be attributed to differences in cost attribution among different accounting systems but are also evident within the relatively standardized accounting standards required by the Centers for Medicare and Medicaid Services (CMS). Whether such variations result from differences in efficiency or differences in accounting practices is often not clear.

Third-party reimbursements to hospitals and surgeons reflect contractual agreements and, like charges, also do not reflect costs.

Table 1 lists ways to categorize health care costs. Cost traceability and its behavior in relation to output or activity are particularly important concepts for surgeons and hospitals.¹⁵ Examples of direct costs are salaries, supplies, rents, and utilities, whereas indirect costs might be depreciation and/or administrative costs associated with regulatory compliance. Yet these definitions are not cast in stone, and some indirect costs might be considered direct costs depending on the cost objective.

Cost behavior relative to an output or activity costs can be variable, fixed, semivariable, or semifixed. Variable costs (e.g., supplies) change in a constant, proportional manner with changes in output, whereas fixed costs (e.g., equipment) do not change in response to changes in volume. Semivariable costs (e.g., utilities) include elements of both fixed and variable costs: there is a fixed basic cost per unit of time and a direct, proportional relation between volume and cost. Semifixed costs (also known as step costs) also change with changes in output, but the changes occur in discrete steps rather than linearly. An example of a semifixed cost is the number of full-time equivalents (FTEs) needed to run one operating room; labor costs will be constant whether that room is used all the time or part-time. Conversely, when operating room use is reduced, there may not be any cost savings until a room is completely taken out of service. Unless the step threshold is attained, costs do not change.

Physicians affect hospital costs primarily via their impact on fully variable and semifixed costs. Such costs typically constitute 15 to 35% of total hospital costs, and this range often reflects substantial variations in the use of resources among surgeons for similar types of patients or procedures.

Table 1 Categories and Types of Hospital Costs

Category	Type	Example or Definition
Traceability to the object being costed	Direct	Salaries, supplies, rents, and utilities
	Indirect	Depreciation and employee benefits
Behavior of cost in relation to output or activity	Variable	Supply
	Fixed	Depreciation
	Semivariable	Utilities
	Semifixed	Number of full-time equivalents per step in output
Management responsibility for control	—	Often limited to direct, variable costs
Future versus historical	Avoidable costs	Costs affected by a decision under consideration
	Sunk costs	Costs not affected by a decision under consideration
	Incremental costs	Changes in total costs resulting from alternative courses of action
	Opportunity costs	Value forgone by using a resource in a particular way instead of in its next best alternative way

This variability, in turn, can affect the “profitability” of a given disease-related group (DRG). Hospital administrators often are aware of this variability but seem reluctant to bring it to a surgeon’s attention. Physicians also affect fixed costs as they influence investments in technology. This is discussed in greater detail in a later section.

Perspectives on costs also vary among payers (e.g., insurers), providers, and patients.¹⁶ Payers’ perspectives primarily focus on the impact of price and use, a perspective exemplified by the introduction of laparoscopic cholecystectomy.¹⁷ Lower per procedure hospital costs were offset by an increase in procedure volume and an increase in aggregate costs to payers. This effect often accounts for differing opinions among patients, providers, and insurers regarding the value of new technology. In this context, regional variation in per capita Medicare spending appears to be more related to differences in use than in price.¹⁸

The interval between an intervention and the point of measurement may also affect estimates of value.^{19,20} Patients are likely to view outcomes over the long term, whereas providers and purchasers tend to have a shorter horizon (e.g., the term of a health care contract). To improve the comparability of cost-effectiveness, the Panel on Cost-Effectiveness in Health and Medicine (a nonfederal panel with expertise in CEA, clinical medicine, ethics, and health outcomes measurement convened by the US Public Health Service) recommended that calculations of cost-effectiveness be based on a broad societal perspective rather than on that of patients, providers, or insurers. Such a perspective would more likely include costs incurred by patients or others (e.g., outpatient medication or home care after hospital discharge).

Defining Quality in Health Care

Assessing cost-effectiveness also requires suitable measures of quality. Unfortunately, defining quality can be even more complex than assessing cost.^{21,22} Measures such as operative mortality are straightforward but have become increasingly rare; therefore, mortality alone is not useful in the vast majority of cases.

A long-held standard of health care quality was the appropriateness of care, and an individual physician’s knowledge was the authority with regard to judging quality. In recent decades, several factors have seriously undermined appropriateness (and perhaps even physician authority) as a primary indicator of quality. These factors included findings that some procedures had a high incidence of inappropriate indications; judgments as to appropriate care relative to groups differed from such judgments relative to individuals²³; retrospective assessments often judged appropriateness on the basis of outcome without considering processes of care²⁴; and a realization that variations in procedure frequency often related to provider capacity (e.g., the number of hospital beds per 1,000 persons). Unexplained variations in the use of health care services across small geographic areas, in particular, have undermined physician authority on quality and are discussed in more detail in a later section.

The overall consequence is that appropriateness is not sufficiently granular to be a useful measure of quality. These shortcomings were addressed by Donabedian, who characterized quality in terms of structure (faculties, equipment, and

services), process (content of care), and outcomes.²⁵ These three components can be measured more objectively than appropriateness and allow application of the quality control techniques pioneered in industry by W. Edwards Deming. These techniques minimize variation in quality by examining production systems. The analogy to health care is that the production systems are the systems of care; the health care systems’ structure and processes are independent variables, and patient outcome is a dependent variable.

Although outcomes are unquestionably a more definitive measure of quality than process, the nature of health care is such that measuring processes of care (i.e., what is done to a patient) may be more immediately relevant to improving the quality of care than measuring outcome per se (i.e., what happens to a patient). One reason for placing greater emphasis on process in health care is that all the factors that affect outcomes in biologic systems may not be known or controllable. This differs from mechanical systems such as aircraft, where a given perturbation has a fairly predictable result. Conversely, the adaptability inherent in biologic systems means that a poor outcome may not occur every time there is an incorrect decision or an error in process.²⁶ Another reason to identify critical processes of care is that it avoids the methodological problems of risk-adjusting outcomes and/or the statistical limitations of comparing outcomes for low-frequency procedures and/or events.

Ultimately, efforts to improve quality will need to account for outcomes, but attempts to improve outcomes without consideration for the relevant processes are likely to prove frustrating. Therefore, it is critically important to identify processes that have the greatest impact on outcomes²⁷; the time and effort spent measuring processes not directly linked to outcomes are likely to be wasteful. The ARRA seeks to promote the burgeoning field of cost-effectiveness research, which informs health care decisions by providing evidence on the effectiveness, benefits, and harm of different treatment options, whether they are drugs, medical devices, surgical procedures, or ways to deliver health care. Evidence can come from existing data or by generating new evidence.

Connecting the Dots: Linking Quality to Systems of Care

Given the importance of processes of care, a surgeon’s (or hospital’s) systems of care reflect the consistency with which the same processes of care are applied to a given situation. Indirect evidence for this link comes from data on the relationship between volume and outcomes for complex procedures; surgeons and/or hospitals that do a given operation more frequently (i.e., high volumes) often have better outcomes.^{28–33} Moreover, the relative impact of hospital volume and surgeon volume on outcomes can vary by procedure. Thus, complex, team-dependent procedures such as cardiac surgery, pancreatectomy, and esophagectomy have a stronger relation with hospital volume even if performed by low-volume surgeons; by comparison, carotid endarterectomy and thyroidectomy have a strong relation with surgeon volume. A positive relation with outcomes also has been noted for surgical subspecialty training.^{28,32,34}

These volume-outcome relations data are intriguing, although they only represent associations and probabilities, not cause-and-effect relationships.³⁵ This raises the question

of whether practice makes perfect or perfect makes practice. The answer is not known but has produced two schools of thought. The practice makes perfect school of thought advocates that quality improvements on a widespread basis will derive from the adoption of better systems or processes of care. These proponents note that low volume is not always associated with worse outcomes, and high volume is not always associated with improved outcomes. Thus, the findings apply to surgeons in general but not to specific surgeons. This means that good outcomes can be achieved even with low volumes if carried out using good systems. Conversely, high volumes may result in worse outcomes in the presence of poor systems. As a further caveat, the relative applicability of the role of systems to complex care is suggested by findings from the Department of Veterans Affairs' (VA) National Surgical Quality Improvement Project (NSQIP). One study of eight common surgical procedures noted no correlation between hospital operative volume and postoperative mortality.³⁶

In comparison, the perfect makes practice school advocates regionalizing care to those centers with better outcomes. Perhaps the best known of these advocates is the Leapfrog Group (www.leapfroggroup.org), a large consortium of major employers. They used empirical observations of cost and outcomes to identify the minimum volumes for procedures such as coronary artery bypass grafting, esophagectomy, carotid endarterectomy, and aortic aneurysm repair that were associated with optimal outcomes. The empirical basis of these determinations is subject to methodological problems.³⁷ Moreover, changes in technology, such as the advent of endovascular aortic aneurysm repair, have substantially undermined the experience levels that were the basis of the original recommendations.

Other proponents of regionalization are the Institute of Medicine's National Cancer Policy Board and the National Research Council. They concluded that complicated cancer operations had better initial outcomes with high-volume providers.³⁸ Higher volumes also were associated with improved long-term survival.

Although regionalization has proven effective in trauma care, the basis of the improved quality in this setting may be better systems of care, not higher volume per se.³⁹ Moreover, the perception of preventability of trauma deaths increased in parallel with the appreciation of the importance of the system. Thus, regionalization of care without a solid understanding of the basis of the volume-outcome relation has the potential to create unintended or adverse consequences for overall care. Consequently, many believe that it is too soon to use volume-outcome data as a surrogate for quality or as criteria for establishing policy.⁴⁰ The higher quality of care at level I trauma centers comes with a price; these centers' better outcomes are also more expensive.⁴¹ This reflects both the relative and absolute aspects of cost-effectiveness. Regionalization of trauma care appears to be cost-effective relative to lack of regionalization, with an associated incremental cost of less than \$50,000/life-year saved (LYS); LYS is a measure of the number of life-years saved as a result of a health intervention. The \$50,000 figure is a threshold conventionally used to ascertain cost-effectiveness. A corollary is that cost-effectiveness does not always equate to cost saving.

Linking Processes to Performance

The desire to link processes to performance has become manifest in pay-for-performance (P4P) programs that provide incentives to adopt evidence-based process measures.^{42,43} The most conspicuous of these is Medicare's Physician Quality Reporting Initiative (PQRI) (www.cms.hhs.gov/pqri). The list of applicable measures has expanded considerably in the last several years, and some specific measures related to surgical care are listed in Table 2. A recent notable finding is that the infection control measures of the Surgical Care Improvement Project (SCIP), which are closely aligned with similar PQRI measures, appear to be most effective when used in the aggregate rather than as individual measures.⁴⁴

Although the rationale for these programs seems straightforward, there are concerns about their long-term potential effectiveness. One such concern is that only a small number of surgical process measures have been identified so far. In addition, these measures tend to be related to general aspects of care, with many processes of care more specific to the outcome of a given procedure or disease process yet to be identified.

There are also concerns that the magnitude of the cost reductions relative to the incentives is presently not known. This is particularly relevant if health care finance is a zero-sum game. If incentive payments exceed the savings, there will be increased pressure to reduce other payments to maintain budget neutrality. If the savings exceed the incentives, there may be increased pressure to increase the incentives.

A further concern relates to assigning the benefits from P4P. Surgeon-related quality improvements that appear to confer disproportionate financial benefits on the insurer rather than on the surgeon may reduce the incentive for surgeons to implement improvements. This concern also relates to P4P measures where implementation requires coordination of systems among providers rather than an isolated action on the part of an individual or an institution. For example, compliance with the measures for prophylactic antibiotics may reward or penalize a surgeon even though she or he may have little control over whether antibiotics are given in a timely fashion; the hospital systems needed for compliance may be a more important determinant of compliance with this measure. Indeed, one study found that a major barrier to compliance was that no single participant in the perioperative routine had acknowledged responsibility to administer prophylactic antibiotics.⁴⁵ The need for coordination among individuals in such situations has been recognized among commercial health maintenance organizations' (HMOs) P4P programs: only 13.3% of the physician-oriented programs focus solely on the individual physician as the unit of payment.^{42,43} The need for such coordination has raised concern that the dispersion of patient care among multiple physicians could limit the effectiveness of initiatives that rely on a single retrospective method for assigning responsibility.⁴⁶

Another concern is that P4P may not be so much pay for performance as it is pay for compliance. It is argued that the real goal should be to encourage innovation to optimize cost-effectiveness. Moreover, not all P4P programs focus on evidence-based measures. For example, one study found that 24% of physicians faced incentives derived from patient satisfaction surveys and 14% faced incentives derived from

Table 2 Current Physician Quality Reporting Initiative Measures by Surgical Specialty

General and Perioperative Measures, All Specialties

- 20. Perioperative Care: Timing of Antibiotic Prophylaxis — Ordering Physician**
Percentage of surgical patients aged 18 years and older undergoing procedures with the indications for prophylactic parenteral antibiotics, who have an order for prophylactic parenteral antibiotic to be given within 1 hour (if fluoroquinolone or vancomycin, 2 hours) prior to the surgical incision (or start of procedure when no incision is required)
- 21. Perioperative Care: Selection of Prophylactic Antibiotic — First- OR Second-Generation Cephalosporin**
Percentage of surgical patients aged 18 years and older undergoing procedures with the indications for a first- OR second-generation cephalosporin prophylactic antibiotic, who had an order for cefazolin OR cefuroxime for antimicrobial prophylaxis
- 22. Perioperative Care: Discontinuation of Prophylactic Antibiotics (Noncardiac Procedures)**
Percentage of noncardiac surgical patients aged 18 years and older undergoing procedures with the indications for prophylactic parenteral antibiotics who received a prophylactic parenteral antibiotic and have an order for discontinuation of prophylactic parenteral antibiotics within 24 hours of surgical end time
- 23. Perioperative Care: Venous Thromboembolism (VTE) Prophylaxis (When Indicated in ALL Patients)**
Percentage of patients aged 18 years and older undergoing procedures for which VTE prophylaxis is indicated in all patients, who had an order for low-molecular-weight heparin, low-dose unfractionated heparin, adjusted-dose warfarin, fondaparinux, or mechanical prophylaxis to be given within 24 hours prior to incision time or within 24 hours after surgery end time
- 30. Perioperative Care: Timely Administration of Prophylactic Parenteral Antibiotics**
Percentage of surgical patients aged 18 years and older who receive an anesthetic when undergoing procedures with the indications for prophylactic parenteral antibiotics for whom administration of the prophylactic parenteral antibiotic ordered has been initiated within 1 hour (if fluoroquinolone or vancomycin, 2 hours) prior to the surgical incision (or start of procedure when no incision is required)
- 46. Medication Reconciliation: Reconciliation after Discharge from an Inpatient Facility**
Percentage of patients aged 65 years and older discharged from any inpatient facility (e.g., hospital, skilled nursing facility, or rehabilitation facility) and seen within 60 days following discharge in the office by the physician providing ongoing care who had a reconciliation of the discharge medications with the current medication list in the medical record documented
- 76. Prevention of Catheter-Related Bloodstream Infections: Central Venous Catheter (CVC) Insertion Protocol**
Percentage of patients, regardless of age, who undergo CVC insertion for whom CVC was inserted with all elements of maximal sterile barrier technique (cap AND mask AND sterile gown AND sterile gloves AND a large sterile sheet AND hand hygiene AND 2% chlorhexidine for cutaneous antisepsis [or acceptable alternative antiseptics per current guideline]) followed
- 114. Preventive Care and Screening: Inquiry Regarding Tobacco Use**
Percentage of patients aged 18 years or older who were queried about tobacco use one or more times within 24 months
- 115. Preventive Care and Screening: Advising Smokers and Tobacco Users to Quit**
Percentage of patients aged 18 years and older who are smokers or tobacco users and who received advice to quit smoking
- 124. Health Information Technology: Adoption/Use of Electronic Health Records (EHRs)**
Documents whether provider has adopted and is using health information technology. To qualify, the provider must have adopted and be using a certified/qualified EHR.
- 193. Perioperative Temperature Management**
Percentage of patients, regardless of age, undergoing surgical or therapeutic procedures under general or neuraxial anesthesia of 60 minutes' duration or longer, except patients undergoing cardiopulmonary bypass, for whom either active warming was used intraoperatively for the purpose of maintaining normothermia or at least one body temperature $\geq 36^{\circ}\text{C}$ (or 96.8°F) was recorded within the 30 minutes immediately before or the 15 minutes immediately after anesthesia end time

Cardiac Surgery

- 43. Coronary Artery Bypass Graft (CABG): Use of Internal Mammary Artery (IMA) in Patients with Isolated CABG Surgery**
Percentage of patients aged 18 years and older undergoing isolated CABG surgery using an IMA graft
- 44. Coronary Artery Bypass Graft (CABG): Preoperative Beta Blocker in Patients with Isolated CABG Surgery**
Percentage of patients aged 18 years and older undergoing isolated CABG surgery who received a beta blocker within 24 hours prior to surgical incision
- 45. Perioperative Care: Discontinuation of Prophylactic Antibiotics (Cardiac Procedures)**
Percentage of cardiac surgical patients aged 18 years and older undergoing procedures with the indications for prophylactic antibiotics who received a prophylactic antibiotic and who have an order for discontinuation of prophylactic antibiotics within 48 hours of surgical end time
- 164. Coronary Artery Bypass Graft (CABG): Prolonged Intubation (Ventilation)**
Percentage of patients aged 18 years and older undergoing isolated CABG surgery who require intubation > 24 hours
- 165. Coronary Artery Bypass Graft (CABG): Deep Sternal Wound Infection Rate**
Percentage of patients aged 18 years and older undergoing isolated CABG surgery who developed deep sternal wound infection (involving muscle, bone, and/or mediastinum requiring operative intervention) within 30 days postoperatively
- 166. Coronary Artery Bypass Graft (CABG): Stroke/Cerebrovascular Accident (CVA)**
Percentage of patients aged 18 years and older undergoing isolated CABG surgery who had a stroke/CVA within 24 hours postoperatively
- 167. Coronary Artery Bypass Graft (CABG): Postoperative Renal Insufficiency**
Percentage of patients aged 18 years and older undergoing isolated CABG surgery who develop postoperative renal insufficiency or require dialysis
- 168. Coronary Artery Bypass Graft (CABG): Surgical Reexploration**
Percentage of patients aged 18 years and older undergoing isolated CABG surgery who require a return to the operating room for mediastinal bleeding/tamponade, graft occlusion (attributable to acute closure, thrombosis, or technical or embolic origin), or other cardiac reason
- 169. Coronary Artery Bypass Graft (CABG): Antiplatelet Medications at Discharge**
Percentage of patients aged 18 years and older undergoing isolated CABG surgery who have antiplatelet medication at discharge
- 170. Coronary Artery Bypass Graft (CABG): Beta Blockers Administered at Discharge**
Percentage of patients aged 18 years and older undergoing isolated CABG surgery who were discharged on beta blockers
- 171. Coronary Artery Bypass Graft (CABG): Lipid Management and Counseling**
Percentage of patients aged 18 years and older undergoing isolated CABG surgery who have antilipid treatment at discharge

Table 2 Continued

197. Coronary Artery Disease (CAD): Drug Therapy for Lowering Low-Density Lipoprotein Cholesterol Percentage of patients aged 18 years and older with a diagnosis of CAD who were prescribed a lipid-lowering therapy (based on current American College of Cardiology/American Heart Association guidelines)
<i>General Surgery/Colorectal Surgery</i> 185. Endoscopy and Polyp Surveillance: Colonoscopy Interval for Patients with a History of Adenomatous Polyps — Avoidance of Inappropriate Use Percentage of patients aged 18 years and older receiving a surveillance colonoscopy and with a history of colonic polyp(s) in a previous colonoscopy who had a follow-up interval of 3 or more years since their last colonoscopy documented in the colonoscopy report
<i>Ophthalmology</i> 12. Primary Open-Angle Glaucoma (POAG): Optic Nerve Evaluation Percentage of patients aged 18 years and older with a diagnosis of POAG who have an optic nerve head evaluation during one or more office visits within 12 months 14. Age-Related Macular Degeneration (AMD): Dilated Macular Examination Percentage of patients aged 50 years and older with a diagnosis of AMD who had a dilated macular examination performed that included documentation of the presence or absence of macular thickening or hemorrhage AND the level of macular degeneration severity during one or more office visits within 12 months 139. Cataracts: Comprehensive Preoperative Assessment for Cataract Surgery with Intraocular Lens (IOL) Placement Percentage of patients aged 18 years and older with a procedure of cataract surgery with IOL placement who received a comprehensive preoperative assessment of (1) dilated fundus examination; (2) axial length, corneal keratometry measurement, and method of IOL power calculation reviewed; and (3) functional or medical indication(s) for surgery prior to the cataract surgery with IOL placement within 12 months prior to cataract surgery 141. Primary Open-Angle Glaucoma (POAG): Reduction of Intraocular Pressure (IOP) by 15% OR Documentation of a Plan of Care Percentage of patients aged 18 years and older with a diagnosis of POAG whose glaucoma treatment has not failed (the most recent IOP was reduced by at least 15% from the preintervention level), OR if the most recent IOP was not reduced by at least 15% from the preintervention level, a plan of care was documented within 12 months 191. Cataracts: 20/40 or Better Visual Acuity within 90 Days following Cataract Surgery Percentage of patients aged 18 years and older with a diagnosis of uncomplicated cataract who had cataract surgery and no significant ocular conditions impacting the visual outcome of surgery and had best-corrected visual acuity of 20/40 or better (distance or near) achieved within 90 days following the cataract surgery 192. Cataracts: Complications within 30 Days following Cataract Surgery Requiring Additional Surgical Procedures Percentage of patients aged 18 years and older with a diagnosis of uncomplicated cataract who had cataract surgery and any of a specified list of surgical procedures in the 30 days following cataract surgery that would indicate the occurrence of any of the following major complications: retained nuclear fragments, endophthalmitis, dislocated or wrong power IOL, retinal detachment, or wound dehiscence
<i>Orthopedics</i> 24. Osteoporosis: Communication with the Physician Managing Ongoing Care Postfracture of Hip, Spine, or Distal Radius for Men and Women Aged 50 Years and Older Percentage of patients aged 50 years and older treated for a hip, spine, or distal radial fracture with documentation of communication with the physician managing the patient's ongoing care that a fracture occurred and that the patient was or should be tested or treated for osteoporosis 40. Osteoporosis: Management following Fracture of Hip, Spine, or Distal Radius for Men and Women Aged 50 Years and Older Percentage of patients aged 50 years and older with fracture of the hip, spine, or distal radius who had a central dual-energy x-ray absorptiometry measurement ordered or performed or pharmacologic therapy prescribed
<i>Otolaryngology</i> 91. Acute Otitis Externa (AOE): Topical Therapy Percentage of patients aged 2 years and older with a diagnosis of AOE who were prescribed topical preparations 92. Acute Otitis Externa (AOE): Pain Assessment Percentage of patient visits for those patients aged 2 years and older with a diagnosis of AOE with assessment for auricular or periauricular pain 93. Acute Otitis Externa (AOE): Systemic Antimicrobial Therapy — Avoidance of Inappropriate Use Percentage of patients aged 2 years and older with a diagnosis of AOE who were not prescribed systemic antimicrobial therapy 94. Otitis Media with Effusion (OME): Diagnostic Evaluation — Assessment of Tympanic Membrane Mobility Percentage of patient visits for those patients aged 2 months through 12 years with a diagnosis of OME with assessment of tympanic membrane mobility with pneumatic otoscopy or tympanometry
<i>Surgical Oncology</i> 71. Breast Cancer: Hormonal Therapy for Stage IC–IIIC Estrogen Receptor/Progesterone Receptor (ER/PR)-Positive Breast Cancer Percentage of female patients aged 18 years and older with stage IC through IIIC, ER- or PR-positive breast cancer who were prescribed tamoxifen or aromatase inhibitor during the 12-month reporting period 72. Colon Cancer: Chemotherapy for Stage III Colon Cancer Patients Percentage of patients aged 18 years and older with stage IIIA through IIIC colon cancer who are referred for adjuvant chemotherapy, are prescribed adjuvant chemotherapy, or have previously received adjuvant chemotherapy within the 12-month reporting period 99. Breast Cancer Resection Pathology Reporting: pT Category (Primary Tumor) and pN Category (Regional Lymph Nodes) with Histologic Grade Percentage of breast cancer resection pathology reports that include the pT category (primary tumor), the pN category (regional lymph nodes), and the histologic grade 100. Colorectal Cancer Resection Pathology Reporting: pT Category (Primary Tumor) and pN Category (Regional Lymph Nodes) with Histologic Grade Percentage of colon and rectum cancer resection pathology reports that include the pT category (primary tumor), the pN category (regional lymph nodes), and the histologic grade

Table 2 Continued

- 112. Preventive Care and Screening: Screening Mammography**
Percentage of women aged 40 through 69 years who had a mammogram to screen for breast cancer within 24 months
- 113. Preventive Care and Screening: Colorectal Cancer Screening**
Percentage of patients aged 50 through 75 years who received the appropriate colorectal cancer screening
- 136. Melanoma: Follow-up Aspects of Care**
Percentage of patients, regardless of age, with a new diagnosis of melanoma or a history of melanoma who received all of the following aspects of care within 12 months: (1) patient was asked specifically if he/she had any new or changing moles; AND (2) a complete physical skin examination was performed and the morphology, size, and location of new or changing pigmented lesions were noted; AND (3) patient was counseled to perform a monthly self skin examination
- 137. Melanoma: Continuity of Care — Recall System**
Percentage of patients, regardless of age, with a current diagnosis of melanoma or a history of melanoma whose information was entered, at least once within a 12-month period, into a recall system that includes a target date for the next complete physical skin examination AND a process to follow-up with patients who either did not make an appointment within the specified time frame or who missed a scheduled appointment
- 138. Melanoma: Coordination of Care**
Percentage of patients, regardless of age, with a new occurrence of melanoma who have a treatment plan documented in the chart that was communicated to the physician(s) providing continuing care within 1 month of diagnosis
- 157. Thoracic Surgery: Recording of Clinical Stage for Lung Cancer and Esophageal Cancer Resection**
Percentage of surgical patients aged 18 years and older undergoing resection for lung or esophageal cancer who had clinical TNM staging provided prior to surgery
- 194. Oncology: Cancer Stage Documented**
Percentage of patients, regardless of age, with a diagnosis of breast, colon, or rectal cancer who are seen in the ambulatory setting who have a baseline AJCC cancer stage or documentation that the cancer is metastatic in the medical record at least once within 12 months

Urology

- 102. Prostate Cancer: Avoidance of Overuse of Bone Scan for Staging Low-Risk Prostate Cancer Patients**
Percentage of patients, regardless of age, with a diagnosis of prostate cancer at low risk of recurrence receiving interstitial prostate brachytherapy, OR external-beam radiotherapy to the prostate, OR radical prostatectomy, OR cryotherapy who did not have a bone scan performed at any time since diagnosis of prostate cancer
- 104. Prostate Cancer: Adjuvant Hormonal Therapy for High-Risk Prostate Cancer Patients**
Percentage of patients, regardless of age, with a diagnosis of prostate cancer at high risk for recurrence receiving external-beam radiotherapy to the prostate who were prescribed adjuvant hormonal therapy (GnRH agonist or antagonist)
- 105. Prostate Cancer: Three-Dimensional Radiotherapy**
Percentage of patients, regardless of age, with a diagnosis of clinically localized prostate cancer receiving external-beam radiotherapy as a primary therapy to the prostate with or without nodal irradiation (no metastases; no salvage therapy) who receive three-dimensional conformal radiotherapy (3D-CRT) or intensity-modulated radiation therapy

Vascular Surgery

- 126. Diabetes Mellitus: Diabetic Foot and Ankle Care, Peripheral Neuropathy — Neurologic Evaluation**
Percentage of patients aged 18 years and older with a diagnosis of diabetes mellitus who had a neurologic examination of their lower extremities within 12 months
- 127. Diabetes Mellitus: Diabetic Foot and Ankle Care, Ulcer Prevention — Evaluation of Footwear**
Percentage of patients aged 18 years and older with a diagnosis of diabetes mellitus who were evaluated for proper footwear and sizing
- 158. Carotid Endarterectomy: Use of Patch During Conventional Carotid Endarterectomy**
Percentage of patients aged 18 years and older undergoing conventional (noneversion) carotid endarterectomy who undergo patch closure of the arteriotomy
- 163. Diabetes Mellitus: Foot Examination**
Percentage of patients aged 18 through 75 years with diabetes who had a foot examination
- 172. Hemodialysis Vascular Access Decision Making by Surgeon to Maximize Placement of Autogenous Arteriovenous (AV) Fistula**
Percentage of patients aged 18 years and older with a diagnosis of advanced chronic kidney disease (stage 4 or 5) or end-stage renal disease requiring hemodialysis vascular access documented by surgeon to have received autogenous AV fistula
- 186. Wound Care: Use of Compression System in Patients with Venous Ulcers**
Percentage of patients aged 18 years and older with a diagnosis of venous ulcer who were prescribed compression therapy within the 12-month reporting period
- 195. Stenosis Measurement in Carotid Imaging Studies**
Percentage of final reports for all patients, regardless of age, for carotid imaging studies (neck magnetic resonance angiography, neck computed tomographic angiography, neck duplex ultrasonography, carotid angiography) performed that include direct or indirect reference to measurements of distal internal carotid diameter as the denominator for stenosis measurement
- 201. Ischemic Vascular Disease (IVD): Blood Pressure Management Control**
Percentage of patients aged 18 years and older with IVD who had most recent blood pressure in control (less than 140/90 mm Hg)
- 202. Ischemic Vascular Disease (IVD): Complete Lipid Profile**
Percentage of patients aged 18 years and older with IVD who received at least one lipid profile within 12 months
- 203. Ischemic Vascular Disease (IVD): Low-Density Lipoprotein (LDL) Cholesterol Control**
Percentage of patients aged 18 years and older with IVD who had most recent LDL cholesterol level in control (less than 100 mg/dL)
- 204. Ischemic Vascular Disease (IVD): Use of Aspirin or Another Antithrombotic**
Percentage of patients aged 18 years and older with IVD with documented use of aspirin or other antithrombotic

The number of each measure is that assigned by the Centers for Medicare and Medicaid Services. Available at: https://www.cms.gov/PQRI/Downloads/2010_PQRI_MeasuresList_111309.pdf. accessed January 10, 2011.
AJCC = American Joint Committee on Cancer; GnRH = gonadotropin-releasing hormone.

profiling based on use of medical resources, whereas 19% faced incentives derived from quality of care measures. Patient satisfaction is undoubtedly important, but it is not clear that improved patient satisfaction alone suffices to address problems of cost-effectiveness.

Lastly, there is the issue of how providers might react when there are differences in P4P programs among the various health plans in which they participate. Many providers would prefer health plans to use a single standardized set of measures, but local market environments can make such standardization unlikely.⁴⁷ As a result, providers may ignore measures that seem to be contradictory, are perceived as too complex, or derive from health plans from which they get relatively few patients. A related concern is that some P4P programs could have unintended negative consequences if physicians are convinced that the program does not incorporate adequate risk adjustment mechanisms. Providers then might simply opt out of seeing challenging patients.^{48,49} To avoid some of these problems, the Agency for Healthcare Research and Quality (AHRQ) has a specific section of their website (www.ahrq.gov/qual/p4pguide.htm) devoted to P4P programs, including a decision guide for purchasers.

P4P and “value-based purchasing” are incentive payment or shared savings programs that are related to “gainsharing.” The Office of the Inspector General (OIG) has defined gainsharing as an “arrangement in which a hospital will share with each physician group a percentage of the hospital’s cost savings arising from the physician groups’ implementation of cost reduction methods.”⁵⁰ Although intended to encourage physicians to deliver quality care, such gainsharing arrangements can technically look like a model of a kickback; moreover, they are barred by the civil monetary penalty law, which prohibits hospitals from rewarding physicians for reducing services to patients. The Deficit Reduction Act of 2005 directed the CMS to conduct demonstration projects, and these are now under way.

These programs notwithstanding, substantial direct evidence of the link between systems and quality comes from the quality improvement efforts of organizations that analyze and standardize systems of care. Perhaps the most notable of these efforts is the multi-institutional Northern New England Cardiovascular Disease Study Group (NNECVDSG).⁵¹ This group began in 1990 and consisted of cardiac surgical teams (e.g., surgeons, nurses, anesthesiologists, pump technicians) that received feedback on outcomes, were trained in Deming’s quality improvement techniques, and site-visited other participating centers. They also periodically met to share data and discuss processes of care. The result has been to substantially reduce morbidity and mortality from cardiac surgery and to minimize the year-to-year mortality variations among the institutions. They also had a low incidence of procedures that did not adhere to recommended indications for surgery.⁵²

The group’s success can be attributed to several characteristics: there is no ambiguity of purpose, the data are not owned by any member or subgroup of members, members have an established safe place to work, a forum is set up for discussion, and there is regular feedback. This was achieved without personal criticism or an attempt to identify any proverbial “bad apples.” Despite concerns that the findings would lead to unfavorable publicity, this did not occur. Three

important conclusions to be drawn from these efforts are as follows: physician-initiated interventions can be as effective as external review (and possibly more effective) in improving quality; a systems approach to quality improvement is better than a bad apple approach; and it is possible to conduct quality improvement programs involving practice groups that might otherwise be viewed as competitors.

The VA’s NSQIP is another example of a successful quality initiative, achieving a 27% reduction in 30-day mortality after major procedures and a 45% decrease in morbidity.⁵³ NSQIP found the two most important risk factors for prolonged hospital stay after major elective surgery to be the intraoperative processes of care and postoperative adverse events.⁵⁴ Notably, the savings from improved surgical care far exceeded investment in the project.⁵⁵ NSQIP has now expanded into the broader community under the auspices of the American College of Surgeons (ACS). NSQIP data also have been used to validate the AHRQ Patient Safety Indicators (www.academyhealth.org/2005/ppt/tsilimingras.ppt).

Other successful surgically related quality improvement efforts include Intermountain Health Systems in Utah; the Maine Medical Assessment Foundation⁵⁶; the Washington State Surgical Clinical Outcomes Assessment Program (SCOAP)⁵⁷; Quality Surgical Solutions in Kentucky⁵⁸; the Michigan Surgical Quality collaborative⁵⁹; the Society for Thoracic Surgery national database, which is now widely accepted as a benchmark for quality in cardiac surgery⁶⁰; the New England Colorectal Cancer Quality Project⁶¹; the Vascular Study Group of Northern New England⁶²; and the National Surgical Infection Collaborative.⁴⁵

The Maine and Michigan efforts are notable in that they have been carried out in conjunction with insurers.^{63–65} Moreover, none of these efforts increased liability exposure; indeed, they often reduced it. Because the practice profiles were physician initiated, there was little risk that the findings would be used to make decisions about credentialing, reimbursement, or contracting.⁵⁶ It is also noteworthy that the parties that funded these efforts (including insurers) usually agreed to confidentiality in return for the benefit associated with voluntary physician involvement.

Measuring Health Outcomes

As noted above, the primary goal of investigating the structure and process components of care is, ultimately, to improve outcomes. Using outcomes to assess quality can be confounded by a number of factors, however. One such factor is the reduced usefulness of traditional metrics. For instance, mortality is infrequent with most surgical procedures, and morbidity such as wound infection rates can be difficult to assess in an era of early discharges. Other short-term outcome metrics, such as length of stay, readmission, or return to work, are often influenced by deeply rooted social and economic factors. A further issue is that many measures of quality lack standard definitions.⁶⁶

Another factor confounding the measurement of health care outcomes has been the growth of knowledge and technology that has increased surgical care related to chronic and/or degenerative diseases. Recent data show that 133 million people, or almost half of all Americans, live with a chronic condition.⁶⁷ That number is projected to increase by more

than 1% per year by 2030, resulting in an estimated chronically ill population of 171 million. Moreover, almost half of all people with chronic illnesses have multiple conditions. Integrated health care delivery via the chronic care model is intended to address the many deficiencies in the current management of diseases such as diabetes, heart disease, depression, and asthma. Traditional measures of quality (e.g., 30-day mortality) that are applied to acute conditions such as perforated ulcer are not as applicable here. Given that the number and complexity of treatment options for many surgical conditions have increased, it has become necessary to identify quality metrics for each treatment strategy. There also is increasing emphasis on patient-centered care; given the multicultural nature of US society, the result is substantial heterogeneity in patient perspectives on quality. Overall, there has been little research (i.e., clinical trials) on the quality perspectives of vulnerable populations.

Health care quality in this context is typically assessed in terms of quality-adjusted life years (QALYs),^{68,69} a measure that reflects the length of time during which a patient experiences a given health status. The lexicon of research in this area is extensive. Cost-utility analysis is the form of CEA of alternative interventions where costs are measured in monetary units and outcomes in terms of patient utility, usually to the patient, in QALYs. A patient utility is the relative desirability or preference from the patient's perspective for a given health outcome. QALYs are units of health outcomes that adjust gains or losses of years of life subsequent to a health care intervention by the quality of life during those years. Other (although less frequently employed) measures for patient utilities include disability-adjusted life-years (DALYs) and health-year equivalents (HYEs). DALYs are units of health status adjusting age-specific life expectancy by loss of health and years of life attributable to disability from disease or injury, whereas HYE are the number of years of perfect health considered to be equal to the remaining years of life in their respective health states.

QALYs are applicable to assessing surgical outcomes. They can be calculated by several different methods; some include objective measures (e.g., functional status), whereas others only consider subjective estimates of well-being. Even the objective measures consider patient-desired outcomes to capture the meaningfulness of a given functional status. For instance, a patient may not be able to walk as far as another, but whether the former has a worse quality of life depends on each patient's lifestyle.⁷⁰ The result is that QALYs data tend not to follow a normal distribution, and comparative analyses often require use of nonparametric techniques.⁷¹

Estimates of QALYs can be affected by other factors.^{26,72} For instance, estimates of the future value of an outcome measure may vary with the prevailing circumstances at the time of assessment (e.g., acute pain) or with the patient's age (e.g., elderly patients often place great value on the ability to live independently). Calculation of QALYs may also be affected by gender, ethnicity, socioeconomic status, religious beliefs, time away from work, and other factors that affect attitudes about health care. One study noted that surgeons tended to underestimate the importance of patients' social and spiritual themes.⁷³ Adjusting outcome measures to account for health status and severity of illness before treatment also can be difficult.⁷⁴

As with other aspects of cost-effectiveness, estimates of QALYs are confounded by different perspectives among patients, providers, and payers with regard to the experiential, physiologic, and resource-related dimensions that should apply. Thus, the weight given to clinical probabilities, patient utilities and preferences, and cost will affect the calculations. Assessment of quality is further complicated when there is no consensus across perspectives with regard to the preferred strategy or outcome. Finally, quality of life studies can be compromised by other methodological flaws, such as a relative paucity of validated instruments for measuring health-related quality of life, especially in certain specialty areas.⁷⁵ In this context, a 2008 review could not identify a fully validated instrument for assessing postoperative recovery.⁷⁶

INTERPRETING AND/OR INITIATING COST-EFFECTIVENESS ANALYSES

A primer to initiate and/or interpret CEA is available at www.acponline.org/shell/cgi/printhappy.pl/journals/ecp/sepect00/primer.htm.

Several important principles that must be considered when performing and/or interpreting a CEA are the comparison, perspective, direct and indirect costs, time horizon, discounting, and sensitivity analyses.^{77–79} The specific comparison between one health care intervention and another should be precisely defined at the outset of the analysis. Alternative perspectives are of society overall (favored by many), a third-party payer, a physician, a hospital, or a patient. CEA should incorporate two types of cost; direct costs represent the value of all goods, services, and other resources consumed in providing health care or dealing with the side effects of the care, whereas indirect costs (or productivity losses) include the costs of lost work attributable to absenteeism or early retirement, impaired productivity at work, or premature mortality. Intangible costs (i.e., pain, suffering, and grief) are often omitted, which is an important limitation of most CEA. The time horizon of a CEA is the time frame of the study and should be long enough to capture streams of health and economic outcomes; depending on the research question, the time horizon might encompass a disease episode, patient life, or even multiple generations. Discounting allows the model to account for the effect of the passage of time on the values of costs and outcomes, such that costs and outcomes are discounted relative to their present value (e.g., at a rate of 3 to 5% per year). Inflation should be a separate consideration. Finally, sensitivity analyses should be performed to determine if plausible variations in the estimates of certain variables thought to be subject to significant uncertainty affect the results of the cost analysis.

Lower values of cost-effectiveness are understood to be “more cost-effective” or have “increased cost-effectiveness.” In contrast “less cost-effective” and “decreased cost-effectiveness” refer to higher costs per LYS. Cost-effectiveness that has a negative value implies that money would be saved.

Particular points that warrant consideration are as follows:

- CEA is highly sensitive to the choice of compared strategies: it often involves marginal benefits, and excluding a simple strategy in which the only comparison is between

treatment and no treatment can make a particular strategy appear far more cost-effective than it otherwise might seem. CEA does not answer the question of which strategy is economically preferred; rather, it identifies which strategy is more effective in terms of LYS for a given expenditure.⁸⁰

- The quality of supporting evidence is another important consideration. Data garnered in real practice or from a registry are more likely to be generalizable than data that are modeled or collected from a clinical trial.
- Determinations made under optimal circumstances (efficacy) tend to overestimate cost-effectiveness compared with determinations made under real-world conditions (true effectiveness). This distinction between efficacy and effectiveness is reflected in how differences in postoperative stroke rates influence the cost-effectiveness of carotid endarterectomy. Randomized, controlled trials (RCTs) show this procedure to be efficacious when performed by surgeons, with low rates of perioperative stroke and death. As the incidence of stroke and other complications increases with more general use, the procedure becomes less effective or even ineffective.^{81–83} If effectiveness can vary over a relatively narrow range of outcomes, there is a strong ethical motivation for surgeons to be familiar with their own clinical outcomes and seek their patients' informed consent based on their personal results.⁸⁴ In this context, differences in quality or cost measures may be more a function of patient mix than the abilities of the wider surgeon population.
- There needs to be awareness of recent concerns that there may be a bias related to the funding of the study.

These and other considerations require surgeons to possess fundamental skills related to critical analysis of the medical literature, technology assessment, use of diagnostic testing, and clinical decision analysis. Specifics on these skills are further detailed below.

CRITICAL ANALYSIS OF THE MEDICAL LITERATURE

The medical literature is so expansive that one can keep current only with a small fraction of it. Moreover, the potential value of a given study is assigned a level of evidence based on the study's methodology. Yet even here there are a number of accepted techniques for grading level of evidence that include that from the Centre for Evidence Based Medicine (CEBM; www.cebm.net/index.aspx?o=1025), the U.S. Preventive Health Task Force, or the Grading of Recommendations, Assessment, Development and Evaluation (GRADE) system.⁸⁵ The GRADE Working Group is an international collaboration of guideline developers, methodologists, and clinicians whose recommendations on clinical practice guidelines have been increasingly validated in a number of practice settings. Many guideline organizations and medical societies have endorsed the system and adopted it for their guideline processes. Further discussion of guidelines is in the section on Clinical Guidelines below.

RCTs are at the high end of all these scales, and meta-analyses of RCTs have even higher validity. Still, even RCTs have shortcomings: the reporting methods are not fully standardized; their stringent inclusion criteria tend to limit their

applicability to highly specific groups of patients (e.g., elderly and/or pregnant patients are often excluded); they can be expensive; and the numbers of patients needed for statistical purposes can be impractical. In addition, study findings that might seem to apply to a particular patient may be difficult to reproduce in settings that differ from the controlled conditions of the original trial. Also, the pressure to enroll patients in such trials has, on occasion, led to questionable ethical behavior by the investigators.

Three particularly valuable sources for identifying studies relevant to cost-effectiveness and judging the quality of those studies are MEDLINE (www.ncbi.nlm.nih.gov/PubMed/medline.html), the Cochrane Collaboration (www.cochrane.org), and the CEBM (www.cebm.net). Each site has relative advantages and disadvantages. The Cochrane Collaboration is an international network of epidemiologists and clinicians who systematically review the best available medical evidence; it includes sources not always accessible through MEDLINE but, in contrast to MEDLINE, requires a subscription. Recent Cochrane Collaboration reviews are abstracted monthly in the *Journal of the American College of Surgeons* (JACS).

The ACS also makes several literature resources available. These include *Selected Readings in General Surgery* (SRGS), a trusted point of reference that is also available in a Web-based version; and *Evidence Based Reviews in Surgery* (EBRS), a Web-based program developed jointly with the Canadian Association of General Surgeons. Each month during the academic year, EBRS presents a clinical and methodological article that teaches critical appraisal skills. More information about these programs is available at www.facs.org. A series of publications by the Evidence-Based Medicine Working Group also provides further insight into critical literature analysis (<http://jamaevidence.com/resource/520>).

The complexities of literature analysis are reflected in a prospective study of the value of computed tomography (CT) in diagnosing appendicitis. This study compared the clinical likelihood of appendicitis (as estimated by the referring surgeon) to the estimated probability of appendicitis (as determined by CT) and the pathologic condition (or absence thereof), which was then confirmed by operation or recovery.⁸⁶ The clinical likelihood of appendicitis was assigned to one of four categories: (1) definitely appendicitis (80 to 100% likelihood), (2) probably appendicitis (60 to 79%), (3) equivocally appendicitis (40 to 59%), and (4) possibly appendicitis (20 to 39%). The real-life observed incidence of appendicitis in these four categories was 78%, 56%, 33%, and 44%, respectively. Thus, CT interpretations had a sensitivity of 98%, a specificity of 98%, a positive predictive value of 98%, a negative predictive value of 98%, and an accuracy of 98% for either diagnosing or ruling out appendicitis.

Although these results may seem relatively clear-cut, it is possible that the study could have yielded different results and reached other conclusions if it had been performed at another institution. For example, the clinical diagnosis of appendicitis is more accurate among men than among women, and, as a result, the relative value of CT scanning will vary according to the gender distribution of the study group. Also, variability in the estimates of the clinical likelihood of appendicitis among surgeons in that institution, the availability of less expensive alternatives to in-hospital observation, and

use of the emergency department for triage all might lead to substantially different results. The impact of variability in clinical estimates of appendicitis is reflected by the fact that in this report, 53% of the patients had appendicitis; in contrast, other studies have shown that only 30% of patients with an admitting diagnosis of appendicitis eventually underwent appendectomy.⁸⁷ The impact of the accuracy of CT or ultrasonography on negative appendectomies also has been reported.⁸⁸

Literature analysis also requires a distinction between relative and absolute risk reduction. The degree of relative improvement is a function of the baseline results such that a treatment that reduces the incidence of an undesired outcome from 5% to 4% and a treatment that reduces it from 50% to 40% both achieve a 20% relative reduction in risk. However, the second treatment achieves a 10-fold greater absolute risk reduction. In addition, the cost-effectiveness of these two treatments is likely to be very different. This distinction between absolute and relative improvement is an important aspect of patient-centeredness in decision making. It is particularly relevant to patients' willingness to participate in trials of adjuvant cancer therapy. Their decisions for or against such therapy may be affected more by the potential for absolute benefit than by relative benefit.

Interpretation of the literature also needs to consider disease staging. Earlier diagnosis may appear to improve long-term survival but actually only identifies the condition for a longer time. This is known as lead-time bias, and it can lead to overestimation of disease prevalence.⁸⁹

Literature assessment skills are also needed to keep pace with patients' growing access to medical information. There are tens of thousands of health-related Web sites, and tens of millions of adults find health information online. Patients also get information from poorly monitored sources, such as disease-specific bulletin boards. At least some of this information will be inaccurate, misleading, out-of-date, incomplete, or unconventional.⁹⁰ For example a recent study of thyroid cancer information on the Internet determined that the data pertaining to surgical treatment, in particular, were wanting, and only 38% of Web sites were updated in the previous 2 years. No predictors of quality were identified.⁹¹ Indeed, a study of the methodological quality of economic analyses of surgical procedures concluded that studies of cost-effectiveness in surgery in the medical literature often do not meet established criteria.⁹²

TECHNOLOGY ASSESSMENT

The "technological imperative" reflects a prevailing societal attitude that equates the latest with the best and creates considerable pressure to acquire the newest equipment and techniques, even before its value is evident. The explosive growth of technology in recent years has been a particularly important contributor to the rapid growth of health care costs.^{93,94} Although many technological advances have undeniably improved surgical care, some new technologies do not prove to be useful. Accordingly, surgeons need to know how to make decisions about technology acquisition⁹⁵ and how they may contribute to excess capacity and increase health care costs. The problem begins with providers who succumb to the technological imperative before a technology's value is

fully known. Other providers, fearful of being left behind, then follow suit. If the new technology is beneficial, capacity may grow to the point that it exceeds community's needs; if not beneficial, injudicious adoption severely reduces cost-effectiveness. Although some advocate competition among providers as a way of restraining health care costs, competition driven by the technological imperative can contribute to inflationary increases in these same costs. A further consideration is the opportunity costs related to differences in efficiency among competing surgical devices.⁹⁶

Innovations that involve new applications of existing technology are a particular challenge.⁹⁷ Laparoscopic cholecystectomy is a striking example of an existing technology that was rapidly and widely adopted into a new surgical procedure before its nuances were fully appreciated or mastered. Although now a relatively safe procedure, the learning curve of laparoscopic cholecystectomy was associated with a number of bile duct injuries; it is conceivable that at least some of these adverse events could have been avoided had the procedure been introduced in a more systematic fashion. Important lessons here come from a study that analyzed the time needed to learn minimally invasive cardiac surgery.⁹⁸ Fast-learning teams were characterized by members who worked well together in the past, had gone through the early learning phase together before adding new members, scheduled several of the new procedures close together, discussed each case in detail beforehand and afterward, and carefully tracked results. Notably, surgeons on the fast-learning teams were less experienced than those on the slow-learning teams but were more willing to accept input from others on the team.

Given this background, there are a number of questions that should be asked whenever a new technology or an innovation in surgical care is being considered:

- Has the new technology or innovation been adequately tested for safety and efficacy?
- Is the new technology or innovation at least as safe and effective as existing, proven techniques?
- Is the individual proposing to perform the new procedure fully qualified to do so? This raises issues pertaining to surgeon education, skill acquisition, team identification, credentialing, and systems preparation failure.
- Is the new technology effective for the intended purpose? Does the new technology or innovation improve cost-effectiveness?
- Has allowance been made for appropriate patient selection and informed consent?
- What is the appropriate role of industry in new technology education efforts?
- What role do media and public expectations and desires play in driving the application of new technology?

USE OF DIAGNOSTIC TESTING

Laboratory and imaging studies account for a large share of health care costs, and there are substantial variations in the use of such studies. Improving cost-effectiveness goes beyond just being aware of a test's sensitivity (i.e., the ability to identify patients with a disease) and specificity (i.e., the ability to identify patients without a disease). It also depends on the prevalence of the disease in the population in question.⁹⁹ As an example, if a given test has a 98% sensitivity and a 98%

specificity and is applied to a group of patients with a disease prevalence of 10% (i.e., 10% of them has the disease), the results of 49 of 500 patients will be true positives ($500 \times 0.98 \times 0.1$) and 9 ($500 \times 0.02 \times 0.9$) will be false positives. If this same test is applied to a population with a disease prevalence of 1% (a more likely prevalence in the real world), the results of fewer than five of every 500 patients tested ($500 \times 0.98 \times 0.01$) will be true positives and just under 10 ($500 \times 0.02 \times 0.99$) will be false positives. Thus, for any given sensitivity, the ratio of false true positives to true positives increases inversely with disease prevalence.

If this example was applied to a screening test, which if positive might then indicate the need for a riskier downstream test, the likelihood is that an increasing number of false positives would be exposed to the cost and safety risks of the follow-up test without potential benefit. This illustrates the shortcomings of appropriateness as a measure of quality where the relation between health care cost and quality was seen exclusively as positive. Given that complications of downstream tests are just as likely to occur among patients with false positives as among patients with true positives, the net effect of such testing is to decrease the slope of the cost-benefit curve and increase the slope of the cost-harm curve. The differential effects of such testing on these curves alter the relation of quality to cost and produce a negative slope [see Figure 6].¹⁰⁰ This is more than just a theoretical relation as there are now data to show that hospitals' performance on quality of care is not associated with the intensity of their spending.¹⁰¹ Another key point is that the slope between two points represents the incremental changes in cost-effectiveness.⁸⁰ Thus, changes in cost-effectiveness may vary, depending on which portion of the curve is considered.

This effect of disease prevalence on the incidence of false positives establishes a test's value or utility and explains why a test may have relatively little value as a screening test in

general practice (where the disease prevalence is low) but may have high value as a diagnostic tool in a specialty practice (where referrals increase the relative prevalence of the disease). The above calculations illustrate how CEAs can be performed on diagnostic tests and screening techniques as well as more traditional comparisons of treatment.

A specific example of how test utility might affect clinical decision making is that of the functional assessment of incidental adrenal masses.¹⁰² Biochemical testing of patients with these masses in the absence of concrete signs and symptoms may be of relatively little value. Analyses of many other "routine" preoperative tests also suggest that they may add little value.^{103,104} Whether a recent increase in testing noted among cancer patients has added value is unknown.¹⁰⁵

CLINICAL DECISION ANALYSIS

Clinical decision analysis involves identifying and quantifying the effect or impact of each option involved in a diagnostic or therapeutic decision. On the basis of the best estimates available, the outcome of each decision acquires a probability, and each component of the decision tree carries an explicit assumption that allows an appreciation of how specific factors affect the outcome. Management of penetrating colon trauma¹⁰⁶ and treatment of asymptomatic carotid artery stenosis¹⁰⁷ are two examples subject to such analyses. It is important to emphasize that physicians should not feel unduly constrained by these clinical decision analyses; depending on individual patient circumstances, it may be reasonable to give greater consideration to some options and discount others. Thus, decision trees are not intended as absolute mandates but rather as tools for reducing uncertainty and thereby increasing cost-effectiveness.^{108–110}

Some find the mathematics and lexicon of clinical decision analyses intimidating; others may perceive such analyses as exemplifying a "cookbook" approach to health care. Markov modeling involves a set of mutually exclusive states for which there are transition probabilities of moving from one state to another. States have a uniform time period, and transition probabilities remain constant over time, which is often not a realistic circumstance. Nonetheless, it is clear that formal clinical decision analysis yields estimates of the importance of specific facets of health care that might be difficult to obtain otherwise.¹¹¹

PRACTICE GUIDELINES/CRITICAL PATHWAYS

Practice guidelines, also known as critical pathways, intend to indicate the best known processes of care for improving safety and quality. They seek to standardize medical processes, especially in high-volume, high-risk, or complex procedures.¹¹² Such standardization is intended to minimize the variations in practice that imply consequent variations in the cost and quality of care. These pathways are increasingly developed by specialty societies and consensus conferences; they are also available commercially and through focused publications. Online guidelines are available through the National Guideline Clearinghouse (NGC) of the AHRQ at www.guideline.gov or through evidence-based practice centers. Critical pathways seek to improve cost-effectiveness by displaying optimal goals for both patients and providers. The potential benefit of these pathways can be quantified using deviation-based cost modeling.¹¹³

Figure 6 The new concept of quality and cost.⁹⁹ A positive association between quality and cost still exists in zones 1 and 2, but the slope of the curve flattens in zone 3 and actually becomes negative in zone 4. Here, further cost increases are associated with decreasing quality because increased use of sophisticated (albeit riskier) technology in earlier (or even just suspected) stages of disease may result in a flat slope (zone 3) or even a negative one (zone 4).

These guidelines have been criticized on several accounts: the evidence and knowledge needed for such guidelines are often lacking¹¹⁴; there may be a lack of consensus regarding what constitutes “best practice”; guidelines from different sources may be at odds with each other; they may not adhere to established methodological standards^{115,116}; they may become quickly outdated¹¹⁷; they have been criticized as embodying an overly simplistic approach to health care; the focus on quality and efficiency of care is often adopted after a decision has been made to admit a patient or perform a procedure; and they often do not apply to particular patients and can be difficult to use in patients with other, more urgent medical problems. Finally, there are emerging data calling into question whether published practice guidelines are incorporated adequately into all aspects of day-to-day practice, particularly with regard to vulnerable populations, such as the elderly.^{118,119}

In summary, use of these guidelines may not automatically improve quality. Thus, they should best be understood not as rigid rules but rather as ways to codify experiences so that others can avoid mistakes. Accordingly, critical pathways should be considered flexible and should be modified on the basis of experience.

COORDINATION OF CARE

The growing complexity of health care makes teamwork and communication increasingly essential. Lack of coordination can increase costs through the duplication of tests and unnecessary delays; it can also decrease patient satisfaction. One study categorized delays as being attributable to test scheduling (31%), availability of other facilities postdischarge (18%), physician decision making (13%), discharge planning (12%), and surgical scheduling (12%).¹²⁰ Moreover, poor coordination of care is a notable factor in professional liability claims against surgeons.¹²¹

ELECTRONIC MEDICAL RECORDS

Electronic medical records have been advocated as a means of expediting the transfer of important information and improving the coordination of care. Indeed, a key portion of the ARRA was the Health Information Technology for Economic and Clinical Health Act (HITECH), which includes substantial funding for implementation of “meaningful use” of information technology. The goal is to bring US health care fully into the Information Age. To date, the effect of introducing information technology (IT) into hospitals and practices has been a mixed bag. The VA has estimated substantial benefits from its investment,¹²² but the benefit of electronic medical records at private sector hospitals and in private practices appears to be marginal. Electronic medical records are not a panacea, and their benefit in reducing failure to inform patients of clinically significant outpatient tests was greatest in practices that already had good processes for recording progress notes and test results.¹²³

IT is invaluable in improving safety^{124,125} as it facilitates use of strategies to reduce medical errors. Such strategies include tools to improve communication, make information more readily accessible, acquire key pieces of information for subsequent process steps, assist with calculations, perform checks in real time, assist with monitoring information, and provide

decision support.¹²⁶ Studies of computerized clinical decision support systems indicate that practitioners perform better with systems that provide automatic prompts than systems that first require system activation. Such studies also find that there is a greater likelihood of better performance in systems developed by the authors than in those who were not.¹²⁷ Computerized physician order entry has been shown to reduce medication errors¹²⁸ and facilitate ventilator weaning¹²⁹ but is not foolproof and can introduce other types of errors.¹³⁰

Strategies for Improving Cost-effectiveness

It is human nature that every surgeon believes that she or he is among the best. Yet data often show considerable variations in resource use, cost, and outcomes among surgeons. Moreover, these variations cannot readily be accounted for by differences in disease prevalence or severity. Furthermore, areas with higher frequencies of procedures do not have demonstrably better procedure-related health.^{131,132} As a result, these variations are thought to be related more to community signatures or physician uncertainty. Curiously, data on individual surgeon performance are often available to hospital administrators and insurance companies but not the surgeons themselves. The result has been that strategies for cost containment and/or quality improvements often originate at the “blunt” end of a system rather than focusing on direct surgeon involvement. Examples of some of these strategies are outlined in the following sections.

BENCHMARKING CLAIMS DATA

Insurers use claims data to create hospital and physician performance profiles of costs and outcomes. The most favorable data are then used to establish benchmarks. Unfortunately, such benchmarks have limitations. For example, they tend to reflect an ideal or exceptional patient population and may not fully account for severity factors that affect outcome.¹³³ Adjustments for disease severity are particularly difficult to make on the basis of claims data because in many cases, the requisite data either are not collected or are mis-coded.¹³⁴ Medical record review is effective at accounting for severity but is more time-consuming and costly. Even with medical record review, the effects of comorbid conditions on cost and outcome can be difficult to sort out. As a result, it is still difficult to account for much of the cost variation.¹³⁵ Another limitation of benchmarks is that some differences in cost and length of stay are related to factors that are not under surgeons’ direct control, such as patient age, gender, and various cultural, ethnic, or socioeconomic factors extrinsic to the medical care system.^{136–138} Selection bias can affect outcome reporting.¹³⁹ High rates of functional health illiteracy also can adversely affect compliance and thereby outcomes.¹⁴⁰ In the end, some efforts to meet benchmark performance levels actually have the unintended effect of increasing the risk of adverse outcomes in patients with complicated health problems who need more complex care.

PUBLIC REPORT CARDS

Another approach to improving cost-effectiveness has been to distribute provider outcomes directly to the public in the

form of report cards.¹⁴¹ The rationale is that patients armed with this information will choose providers with better outcomes. Such an effort by the CMS (then the Health Care Financing Administration, or HCFA) in the 1980s calculated mortality data for individual hospitals using a risk adjustment model based on DRGs. Subsequently, however, the CMS acknowledged the flaws in the associated mortality model and stopped releasing these data. Subsequently, the CMS (using Medicare data) and some states publicly disclosed provider-specific data on the outcomes of cardiac surgery. Although these efforts used more criteria than were available through DRGs alone,^{142,143} the profiles remained controversial because they still did not adequately account for all the differences in case mix and disease severity. Good surgeons operating on high-risk patients could be adversely affected and less qualified surgeons operating on low-risk patients (or perhaps even without indications for surgery) inappropriately rewarded.

Although release of these data did lower patient mortality, it also might have had the unintended consequence of creating incentives to reduce mortality by avoiding high-risk patients.^{144,145} These report cards also appeared to have limited credibility among cardiovascular specialists.¹⁴⁵ Moreover, the data seemed to be of limited value to the target audience (i.e., patients undergoing cardiac surgery) in that there were few changes in market share among the involved institutions.

The success of provider report cards in prompting quality improvement depends on several factors.^{146,147} These include the strength of the research design and the ease with which the public can understand the text and/or the data display. Despite their shortcomings, use of report cards has now expanded to other specialties. One Web site (www.healthgrades.com) contains hospital outcomes for cardiac, orthopedic, neurologic, pulmonary, and vascular surgery. Transplantation outcomes are also available from the United Network for Organ Sharing (UNOS) at www.unos.org.

To date, evidence supporting a positive effect from these various strategies remains mixed. A 2002 literature review concluded that, based on limited evidence, explicit incentives placing physicians at financial risk appeared to be effective in reducing resource use.¹⁴⁸ However, the empirical evidence regarding the effectiveness of bonus payments on physician resource use was mixed. A more recent review of the value of publicly reported performance data on effectiveness, safety, and patient-centeredness failed to identify conclusive evidence that such reporting was effective.¹⁴⁹ Moreover, only a minority of providers appear to be participating in the PQRI program. This makes it difficult to assess the effect of the program on overall quality. It is still not clear whether the refusal to pay for some “never events” (i.e., shocking medical errors that should never occur) by Medicare¹⁵⁰ and by some private insurers will beneficially impact quality and safety.

Given the limitations of these externally initiated efforts and the remarkable success of physician-initiated efforts noted above, the most difficult step in enhancing cost-effectiveness may be developing a local willingness to initiate the process. Studies of factors associated with practice change in relation to continuing medical education (CME)

consistently emphasize that effective change strategies include reminders, patient-mediated interventions, outreach visits, input from opinion leaders, and multifaceted activities. Specific factors associated with an increased probability of practice change are peer interaction, commitment to change, and assessment of the results of change.^{151–153} Successful activities place substantial emphasis on performance change rather than simply on learning.^{154,155} Additional evidence suggests that improvement in care is more likely to occur with CME activity that is directly linked to processes of care.¹⁵⁶

An underlying tenet from the outset should be that improving cost-effectiveness is an ongoing process akin to peeling an onion: initial steps inevitably lead to deeper analyses. A starting place may be as simple as choosing a particularly bad outcome and taking steps to avoid its occurrence or recurrence. Simple data charts may reveal changes or patterns in outcomes or resource consumption that might not otherwise be obvious. On occasion, merely standardizing a process is sufficient to substantially improve outcomes. With time, strategies for optimal practice are likely to emerge. However, the majority of these efforts are unlikely to eliminate all variations in provider outcomes. For instance, when advances in the care of cystic fibrosis were adopted nationwide, outcomes improved for most centers, but some centers still had better risk-adjusted outcomes than others.¹⁵⁷ Identifying the factors responsible for these remaining differences is a difficult but critical undertaking to achieve the next level of improvement.

Improving Cost-effectiveness in the Operating Room

The operating room is a frequent target for efforts to improve efficiency. Delays in room turnover are a common complaint, the responsibility for which is variously ascribed to nurses, anesthesiologists, and surgeons themselves. Maintaining large inventories to satisfy individual surgeon preferences also contributes to higher costs, and the growth of minimally invasive surgery has added new dimensions to this challenge.¹⁵⁸ Key issues in this setting include reusable versus disposable equipment, variations in the costs of different types of equipment used to accomplish the same task, and just-in-time inventory. Major pieces of equipment often are duplicated to allow similar cases to be performed simultaneously in different rooms, but this duplication often means that the equipment may then be idle for relatively long periods. More efficient use of such equipment reduces costs, but this requires levels of cooperation and coordination among surgical staff members that heretofore have been hard to achieve.

To improve efficiency, surgeons, who have heretofore often been steeped in the view that they are the “captain of the ship,” must embrace the view that all members of the surgical team have interdependent goals for quality, safety, and efficient use of the operating room. Indeed, the team concept requires abandoning the idea that the operating room is staffed by separate surgical, nursing, and anesthesia crews. Models for achieving greater efficiency have been proposed, largely based on the airline industry and aerospace travel coordination.¹⁵⁹ Successful team efforts have led to cost reductions in trauma care^{160,161} and to the development of

protocols to guide ventilator weaning.^{162,163} More human factors research is needed to identify and overcome insidious barriers to human communication.^{164–168}

Ambulatory surgical units often are heralded as cost-effective. However, potential savings are likely to depend on existing operating room capacity and on specific payer issues.¹⁶⁹ By taking less complex cases away from the hospital, there may be fewer cases on which the hospital can amortize fixed costs. Another reason ambulatory surgical units may cost less is that they do not have to maintain standby capability to deal with emergencies. As more surgical procedures are performed on an outpatient basis, there is a growing tension between hospitals and surgeons over the facilities used for such procedures. Independent facilities may be able to eliminate some costs, but they also contribute to excess capacity and probably will not reduce health costs in the long run. This means that sooner or later, surgeons and hospitals will have to address their common interests.¹⁷⁰ Eliminating some of the barriers to gainsharing is likely to facilitate such efforts.

Ethical and Legal Concerns

Efforts to improve cost-effectiveness are often seen as forcing health professionals to face conflicts among the needs of individual patients, the interests of society as a whole, and third parties. Physicians are no strangers to such potential conflicts. Indeed, the vast majority of physicians successfully avoid the temptations inherent in fee-for-service care. The managed care era raised some concerns about conflicts between corporate and patient interests, but these concerns proved to have relatively little foundation and have since abated. Some have suggested that evidence-based data derived from large populations may not readily apply to individual patients, but the rationale for this view is not clear.²³ Thus, physicians should be able to represent both an individual patient's viewpoint and a societal perspective.

The high costs of the terminally ill frequently generate controversy, particularly among patients who require intensive care. To mitigate the dilemmas that may face physicians in making life-ending decisions, increasing emphasis is being placed on patient self-determination. Even the best efforts of physicians and institutions to comply with patient or family choices in the setting of terminal illness may not substantially reduce costs or improve outcomes.¹⁷¹ Actual savings may be small.¹⁷²

Quality in the Aggregate: Small Geographic Area Variation

Earlier in this chapter, it was noted that physician decisions powerfully impact a large proportion of health care costs. The traditional approach has been to honor physicians' deference in such decisions. An increasing challenge to physicians' authority as an arbiter of quality is the long recognized, poorly explained variation in the frequency of surgical procedures among small geographic areas.^{173–175} These variations have been intensively studied and found to remain relatively constant over time. The result is that some communities acquire distinct "surgical signatures"—a finding that supports the

idea that many operative decisions are based on opinion rather than on evidence.¹⁷⁶ This idea is further supported by data indicating that variations in procedure frequency are often procedure specific and inversely related to the degree of consensus regarding indications.¹⁷⁷ Procedures with highly specific indications (e.g., repair of a fractured hip or appendectomy) often show minimal frequency variation, whereas procedures with seemingly less definitive indications (e.g., carotid endarterectomy, hysterectomy, and coronary angiography) often show a great deal of variation.¹⁷⁸ Variations in frequency also can have downstream effects¹⁷⁹; one example of this is the relatively close relation between the intensity of local diagnostic testing and the subsequent performance of invasive cardiac procedures.¹⁸⁰

One issue of debate in interpreting these geographic frequency variations is whether high rates of use are too high or low rates are too low. The association between variation and the ratio of hospital beds to population has raised concerns that low frequency of use may reflect restricted access to care.¹⁸¹ In one study where patients in the aggregate received about half the recommended level of care,¹⁸² a lack of access to health services did not appear to be the underlying problem. To date, efforts to find evidence supporting other possible explanations for these variations (e.g., differences in disease incidence and in the appropriateness of use) have not been successful.¹⁸³

Although some might attribute variations in frequency to the potential conflict of interest inherent in a fee-for-service system, similar variations in procedure frequency are known to occur among VA medical care facilities,¹⁸⁴ as well as in countries that do not have fee-for-service reimbursement.

The current belief is that the high use rates are too high and is supported by findings that patients from areas with widely disparate use rates have comparable health status. These findings have led to the conclusion that "marked variability in surgical practices and presumably in surgical judgment and philosophy must be considered to reflect absent or inadequate data by which to evaluate surgical treatment."¹⁸⁵ This was supported by a study in the 1970s that estimated that only about 15% of common medical practices had documented foundations in medical research.¹⁸⁶ Although this does not necessarily mean that only 15% of care is effective, it does raise concerns about the lack of hard evidence for most care. A more recent estimate is that one third of current health care spending may be wasteful.¹⁸⁷

A related issue is whether these variations should be used to formulate public policy.^{188,189} Some discount these variations by arguing that they are not risk adjusted for differences among patients and cannot predict which will be better at saving lives. Others acknowledge that the Dartmouth analyses are not perfect but are better than other existing methods. Both views agree that these variations should not be used as the sole method to set hospital payment rates and that end-of-life data used for these analyses provide only limited insight into the overall quality of care.

The point is that in addition to misuse, overuse and underuse also can reflect quality. Although there has been some improvement in the adoption of processes of proven value (e.g., the optimal timing and duration of perioperative

antibiotics), overall progress has been disappointingly slow.¹⁹⁰

Reassessing the Relationship between Cost and Quality in Health Care

This chapter sought to emphasize that health care costs do not necessarily have to have a direct relation to quality (i.e., better care does not need to be more expensive). Indeed, higher-quality health care can cost less. Unfortunately, US physicians are more likely than physicians in other countries to report that interventions in patient care geared to cost control were threatening the quality of care they could provide their patients.¹⁹¹ Thus, recognizing that quality does not have to be sacrificed with reductions in cost is essential to overcoming fears that health care reform will adversely affect quality. In this context, it is likely to take time for evidence supporting higher-quality/lower-cost care to evolve. Hopes that such evidence might come quickly have been dashed by reports showing that hospital P4P measures were not strongly associated with better outcomes^{192,193} or produced only modest reductions in mortality.¹⁹⁴ On the positive side, there are studies that show an inverse relation between volume and cost.^{195,196} Thus, high volume might improve cost-effectiveness by affecting both the numerator and the denominator of the equation.

Although it is clear that more data are needed with regard to the relation between cost and quality in health care, an activity likely to bear fruit is reducing costs by reducing the complications of surgical care. A useful approach here may be to consider the added costs of a complication in a given patient with respect to the frequency of that complication in the entire population undergoing a given treatment.¹⁹⁷ The goal is to establish priorities for quality improvement efforts to prevent complications based on both the incidence of the complication and its contribution to resource use.¹⁹⁸

Reassessing the relation between cost and quality may also suffer if there is a relative lack of emphasis on the latter by hospital boards.¹⁹⁹ Similarly, a national survey found that 39% of managed care organizations were moderately or largely influenced in their initial physician selection by previous patterns of costs or use, and nearly 70% profiled their member physicians.²⁰⁰ On the other hand, at least one HMO recognized that practices with high scores on service and quality indicators attracted significantly more new enrollees than practices with lower scores. A challenge in considering both cost and quality is that potential benefits may not occur concurrently. Thus, cost savings may appear before quality improvement, or quality might improve before long-term cost savings are evident.

The Future

All indications are that the efforts to reduce the cost and/or improve the quality of the US health care system will remain strong for the foreseeable future. As an example, large employers increasingly provide incentives to use “high-performance” health provider networks.²⁰¹ Physicians may dispute the validity of cost profiling²⁰² and other challenges to their authority as arbiters of quality; regardless, they will have to bear an

increasing burden of proof as to the quality of care. Moreover, health care payers are likely to address substantial variations in frequency and cost of care by using apparent similarities in quality to contract for less expensive care. How this tension will be resolved remains to be determined. One view is that the pressure on physicians will be based on an assumption by payers that physicians will not knowingly or willingly sacrifice quality. Indeed, some believe that value-based competition may spark physicians to provide care that exceeds patients’ expectations.^{203,204}

In response, physicians need to remain cognizant of a predominant theme of this chapter: physician-led organizations appear to be more successful in improving the cost-effectiveness of care than external policies. Practicing surgeons, who are at the “sharp” end of the system, will need to access data on their performance and participate in the development of better outcome measures. These metrics then can be used to improve performance by redesigning processes of care.²⁰⁵ Physicians need to acknowledge variations in intervention rates and outcomes and to increasingly make medical decisions that are evidence based. They are the best equipped participants in the health care system to identify cost-effective care because they have the necessary knowledge and skill set. If physicians can respond constructively to these challenges, rather than simply ignore or dismiss them, they stand a good chance of recapturing much of their lost stature and autonomy.

In this context, the fee-for-service payment system may be increasingly criticized because it lacks incentives that reimburse physicians based on quality. It seems likely, therefore, that new payment systems will emerge that are more closely linked to quality than the current P4P programs. In one such approach, the Geisinger Health System established incentives through a warranty program for elective cardiac surgery in which there is no added reimbursement for managing complications occurring within the first 90 days after surgery. Geisinger was able to adopt this approach because many of its patients were also insured through the Geisinger system. This eliminated many of the conflicts that might otherwise be present with third-party payers. In creating this program, Geisinger embedded best practices within their processes of care, and the program’s initial success is largely attributed to high compliance rates.²⁰⁶ Interestingly, Geisinger patients insured by other payers also benefit from this system.²⁰⁷

Although such changes may seem daunting, surgeons should recognize that the growing interest in assessing performance is not new. In the early 1900s, Ernest Codman, a Boston surgeon, crusaded for hospitals and surgeons to publicize their results, yet his efforts often met with disinterest, defensiveness, or outright opposition.²⁰⁸ The current call to assess surgeon performance is clearly here to stay. If physicians respond dismissively or defensively (e.g., explaining variations in outcomes by invoking care for sicker patients), they may miss an important opportunity to reestablish their authority on quality. Surgeons who preemptively familiarize themselves with their own outcomes will be better positioned to participate in efforts to improve the cost-effectiveness of surgical care.

8 HEALTH CARE ECONOMICS: THE BROADER CONTEXT

Linda G. Lesky, MD, MA, Robert S. Rhodes, MD, FACS, and Charles L. Rice, MD, FACS*

In a companion chapter [search ACS Surgery for information on cost-effective nonemergency surgical care], we review the principles of cost-effective surgical care and discuss the implications of such principles for health care spending. Our primary focus there is on the interaction between an individual surgeon and an individual patient. In this chapter, we explore some of the issues surrounding health care spending on a larger (i.e., national) scale. It is important for surgeons to have a broad understanding of these issues, in particular because such concerns are increasingly becoming the subject of political debate.

US Health Care Expenditures and Health Outcomes

In 2009, US national health expenditures amounted to \$2.5 trillion (approximately 17.6% of the gross domestic product [GDP]).¹ According to data from the World Health Organization, if the current level of US health care spending were viewed as a separate economy, it would be the seventh largest economy in the world, nearly equal to the GDPs of France and the United Kingdom.² This level of spending translates into a per capita expenditure of \$8,086, which is more than double the average of other Organisation for Economic Co-operation and Development (OECD) countries and which surpasses the per capita expenditure of the next highest-spending country, Switzerland, by more than 30%. Between 1950 and 2001, US per capita spending on health care in constant dollars increased more than 11-fold.

Since the end of World War II, the growth rate of health care spending has exceeded the overall growth of the economy. Although the rate of growth of per capita health care spending has slowed over the past 4 years, there is reason to believe that this slowing trend will be short-lived.³ Over the past 30 years, total national spending on health care has more than doubled as a share of GDP. According to Congressional Budget Office (CBO) projections, total health care spending will reach \$4 trillion by 2015, and in the absence of a significant change in the long-term trends, the share of GDP will double again by 2035, to 31% of GDP. Only a small percentage of this spending growth can be attributed to general inflation, growth in the size of the population, and changes in the age distribution of the population.⁴ The majority is projected to be attributable to rising costs of care and increasing amounts of care.

Economists differ on the extent to which such spending represents a risk to the overall economic well-being of the United States. Those who are concerned about both the amount that is spent on health care and the rate at which this amount is growing cite a number of concerns:

1. In spending more on health care, society spends less on other goods and services—a process referred to as displacement. Thus, health care consumes resources that might otherwise have been allocated to services such as education or public safety.
2. The health care sector of the economy is so large—not only in terms of the amounts of money involved but also in terms of the number of people employed—that short-term changes in its growth rate (in either direction) necessarily exert substantial and painful economic effects. Moreover, the potential magnitude of these effects thwarts political consideration of potential changes to the system.
3. As costs increase, voluntary participation by employers in the provision of health insurance to employees and retirees comes under increasing pressure, with the result that employers either shift more and more of the costs of insurance to employees or decide to stop providing health insurance altogether. Between 2001 and 2006, the contribution of households to health care expenditures increased by more than 35%.³
4. A specific concern also relates to the extent to which spending on Medicare threatens the long-term solvency of the US government. In 2009, Medicare spending grew 7.9% to \$502.3 billion. Absent policy change, the CBO estimates that Medicare spending will grow at an average of 7% each year from 2010 to 2018, rising to \$879 billion annually and 4% of GDP. The rate of growth of Medicare spending over the long term is predicted to exceed the rate of growth of federal revenues and the overall economy,⁵ which most believe is unsustainable. As a result, discussions of health care reform have focused not only on reducing the number of uninsured but also on “bending the health care cost curve” to reduce the rate of growth of health care spending (see below).

Others dismiss these concerns and argue that the health care share of GDP has no natural limit as long as health care is more highly valued than the goods and services that it displaces.⁶ Proponents of this viewpoint distinguish between spending that is affordable (i.e., sustainable) and spending that the country is unwilling to sustain.

The proponents of these two perspectives agree that increases in spending should reflect the increased value placed on health care services relative to non-health care goods and services that are forgone. There is substantial

Financial disclosure information is located at the end of this chapter before the references.

evidence, however, that increased health care expenditures are not invariably associated with demonstrable improvements in health outcomes. Although the United States spends more on health care than any other OECD country, its health status rankings do not compare well with those of other industrialized countries. OECD data indicate that of the 30 OECD countries, the United States has the highest rate of obesity and ranks 15th in infant mortality, 13th in cancer mortality, 21st in mortality from ischemic heart disease, and 15th in life expectancy at 65 years.⁷ An analysis of mortality from causes that were potentially avoidable with timely and effective health care in 19 industrialized countries found that the United States ranked last in the level of decline in these deaths between 1997 and 2002.⁸

Within the United States, several major studies have shown that patients treated in higher-spending regions do not have either better health outcomes or greater satisfaction with their care than patients treated in lower-spending regions.⁹ One such study reported that the differences in spending were largely attributable to the higher frequency of physician visits, the tendency to consult specialists more readily, the ordering of more tests, the performance of more minor procedures, and the more extensive use of hospital and intensive care services in the higher-spending regions. The authors could find no evidence that these types of increased use resulted in improved survival, better functional status, or enhanced satisfaction with care. These findings have profound implications for efforts aimed at containing the further growth of health care spending.

Discrepancy between Costs and Outcomes

Many factors influence the cost of health care and the health outcomes of a population. The increase in the size of the uninsured population is often cited as contributing to poorer health outcomes of US residents and the slow decline in the US amenable mortality.⁸ Wider availability of advanced technology, an increasingly older population, newer and more expensive prescription drugs, inefficiencies in health care delivery, and the rising costs of medical malpractice insurance are all contributors to rising health care costs. However, the single factor that distinguishes health care in the United States from that in other developed countries is the market-based delivery system that characterizes US health care. With the exception of the aging of the population, the health care market influences all of the factors that contribute to the cost of health care and health care outcomes in the United States. A simple review of how the health care market functions reveals why a market-based health care delivery system contributes to rising costs and poor health outcomes.

MODEL OF SUPPLY AND DEMAND

The model of supply and demand is a useful tool for understanding the behavior of buyers and sellers in a market [see Figure 1]. With price on the vertical axis and quantity of a particular good or service on the horizontal axis, the demand curve represents the total demand by all consumers for that good or service. The downward slope of this curve reveals that as price decreases, consumers are willing to purchase more. The demand curve also shows the

Figure 1 The model of supply and demand determines the quantity produced at a given price. Illustrated here is the application of this model to health care. Persons who fall below the equilibrium point on the demand curve cannot afford health care at the market price and must either do without care or seek it in the safety-net health care system. P = price; Q = quantity; Q_d (quantity demanded) = $f_d(P)$ (the demand equation, which includes price); Q_s (quantity supplied) = $f_s(P)$ (the supply equation, which includes price).

amount of a good or service that the market is willing and able to purchase at a given price. Similarly, the supply curve represents the total quantity of a good or service that suppliers are willing to produce at a given price. The point where the two curves intersect represents the equilibrium price and quantity of the good or service.

This equilibrium between supply and demand gives markets their most valued attributes. A competitive market price forces producers to satisfy consumers' demands for a quality product with the least-cost methods of production. Markets also ensure the most efficient and least wasteful allocation of resources in that only the quantity demanded at a specific price is produced. Markets assume, however, that consumers who cannot afford to pay the market price either will find a less expensive substitute product or will do without. They also assume that consumers can be knowledgeable enough about a product to assess its quality and appropriateness for their needs. Finally, markets exist to maximize both the utility of consumers through the purchase of goods and services and the profits of suppliers. Research and the development of innovative products are driven by the opportunity to be the first to enter a market with a new or improved product and thus reap maximum profits.

A key question is whether the features that are normally associated with well-functioning markets in other areas are also applicable to health care. Further analysis of the supply-and-demand model as it relates to the health care market may shed some light on this question.

AFFORDABILITY OF HEALTH CARE

Despite the massive growth of employer-sponsored health insurance, the universal coverage of the Medicare

population over the age of 65, the addition of more than 1 million disabled persons under Medicare, and widespread coverage of the poor under Medicaid, more than 45 million US citizens (almost one of every six) have no health insurance coverage.

Health insurance, in and of itself, leads to distortions in the market because consumers of health care do not see the actual price being paid for health care goods and services. This creates a situation referred to as moral hazard. This term originated with the purchase of fire insurance in the 19th century, when it was recognized that the owner of a property that was insured might have an incentive to incur a loss either by deliberately setting a fire (a moral hazard) or by not taking steps to reduce the likelihood of a fire. The implication of the moral hazard effect for health care spending is that those who are insured (or more generously insured) will tend to use more health services without regard to cost. Insurers seek to reduce the extent of the moral hazard problem by increasing the coinsurance and making the consumer pay a larger share of the full cost.

A more significant economic and ethical concern centers on those persons with no health insurance coverage, who fall below the equilibrium point on the demand curve [see Figure 1]. In a well-functioning market, it is expected that those who cannot afford to pay the market price for a good or service will do without, but our society seems unwilling to allow this when it comes to health care. The result is a patchwork of substitute care that serves the uninsured and underinsured. The so-called safety-net health care system comprises hospitals, community health centers, “free” clinics, and emergency departments. The Institute of Medicine estimated that in 2001, the safety-net health care system cost \$99 billion in direct services and \$65 to \$130 billion in lost productivity.¹⁰ Under current arrangements, the costs of this care are built into the prices charged to those who do have the ability to pay. A 1992 analysis of the distribution of the health care financing burden associated with the US health care system showed that the greatest financial burden fell on those in the middle class: the fourth to seventh income deciles devoted approximately 12% of their cash income to finance health care, whereas the highest income decile devoted about 8%.¹¹

Despite this degree of public spending, the safety-net health care system does not ensure continuity of care or access to all needed care, and as a consequence, the uninsured have poorer health outcomes than those with continuous health insurance coverage.¹² Not only does this safety-net system cost a great deal and result in suboptimal health outcomes for the population it serves, but there is also increasing evidence that in the United States, all patients seeking emergency care for critical conditions wait longer for needed attention as a consequence of overcrowding and the use of emergency departments by uninsured patients who lack a regular source of health care.¹³ The structure of any market assumes that there are those who cannot or will not pay for the good or service at the market price. As long as a market structure for health care delivery is maintained, there will be those who will not have access to appropriate health care.

ASYMMETRICAL KNOWLEDGE

Consumers rely heavily on the advice of their physicians for guidance regarding diagnosis and treatment. In this

setting, not only do physicians function as suppliers of health care services, but they also play a major role in determining the level of demand for these services. For example, physicians advise patients about the frequency of office visits, the types of diagnostic tests to undergo, and the treatment or treatments that may be needed. Asymmetry of knowledge between patients and their physicians forces patients to rely on this advice for health care decisions.

Substantial evidence exists to support the notion that physicians do increase the demand for health care. Supply-and-demand theory dictates that the entry of more sellers into a market should result in increased competition, lower prices, and lower total costs for goods and services. Yet in health care, it has been demonstrated repeatedly that an increased supply of health care services results in an increased demand for services and an increase in costs. Initial concerns about this unusual market behavior stemmed from the observation that in geographic areas that were similar with respect to demographics, socioeconomic characteristics, and burden of disease, hospital use rates were higher in areas with a greater supply of hospital beds.¹⁴ In a study of the supply of surgeons and the demand for surgery, it was estimated that a 10% increase in the supply of surgeons, as measured by the surgeon-to-population ratio, led to a 3% increase in the per capita surgery rate.¹⁵ A number of other studies have addressed the effect of physician ownership on health care use rates. In a study examining the issue of physician ownership of ancillary services, 50% more visits were ordered at physician-owned physical therapy clinics in Florida than were ordered at clinics that received no referrals from owners.¹⁶ The authors of the study could find no discernible difference in the quality of care across ownership structures. An analysis of more than 65,000 insurance claims found that doctors who owned imaging machines ordered more than four times more imaging studies than those who referred to independent radiologists.¹⁷ Finally, in a study addressing the impact of the 1990 Medicare physician reimbursement changes on thoracic surgeons who were predicted to lose substantial income if surgical volumes remained unchanged, the Medicare fee cuts led to volume increases in both Medicare and private-pay patients, to the point where 70% of the fee loss from Medicare was recaptured through higher patient volume.¹⁸

These findings make supplier-induced demand (SID) one of the most controversial issues in health economics. If SID exists to a substantial extent, economic analysis would then suggest that competitive markets are useless as a means of managing health care delivery and reducing costs [see Figure 2]. Although numerous other hypotheses have been offered to explain the empirical findings of the increases in demand associated with increased supply, none disprove SID.

Physicians find the SID hypothesis disturbing because it suggests that they manipulate the demand for health care to advance their own economic interests. Most physicians are aware of the relation between service volume and income, but various other factors (e.g., rapidly evolving technologies, medical uncertainties at all levels of care, and defensive practices to avoid the risk of litigation) make it impossible to determine the exact impact of SID. The concept of target

Figure 2 Given an initial supply and demand for physician services at S_1 and D_1 , assume that the number of physicians increases (arrow 1), thereby shifting the supply curve to the right. In normal economic conditions, the quantity of physician services would increase (to Q_2), and the price would fall (to P_2). Empirical evidence, however, suggests that the demand for services also increases, shifting the demand curve to D_2 (arrow 2) and resulting in an increase in both price (P_3) and quantity (Q_3). D = demand; P = price; Q = quantity; S = supply; subscripts 1, 2, and 3 reflect the order in which quantity and price change in response to a change in supply (arrow 1) followed by a change in demand (arrow 2).

incomes is certainly known to be a factor in other arenas of the economy. Regardless of the true extent of SID's impact on the cost of health care, it is the market-based structure of health care that creates incentives for physicians to influence the demand for health care.

MARKETS, MONOPOLIES, NEW DRUGS, AND TECHNOLOGY

The market is uniquely effective in fostering innovation and technological advances. Firms compete to introduce new products, and in doing so, they gain monopoly power and enhance profits through increased market share and monopoly pricing. Unlike competitive markets, where supply and demand determine the price of a good or service, monopolies set their own price. The profit-maximizing price is achieved by equating the marginal cost of producing one additional unit to the marginal revenue from selling one additional unit [see Figure 3]. This results in a higher price and a lower level of production than would be achieved in a competitive market. Monopoly profits are typically short-lived because as more suppliers enter the market, the marginal revenue curve shifts so that it eventually equals the demand curve, thereby reducing the price and increasing the quantity supplied.

In virtually every other sector of the economy, the introduction of new technology tends to reduce the cost of a particular good or service. Health care is one of the few exceptions to this general rule. A 2003 analysis of the relation between the availability of advanced technologies and health care spending found that for certain technologies (e.g., diagnostic imaging, cardiac catheterization facilities, and intensive care facilities), increased availability was often accompanied by increased use (and hence increased

Figure 3 Monopolies set prices to maximize profits by equating the marginal cost of production and the marginal revenue. This process results in higher prices and lower levels of production than would be found in a competitive market. P_c = competitive price; P_m = monopoly price; Q_c = competitive quantity; Q_m = monopoly quantity.

spending).¹⁹ Similarly, expenditures on prescription drugs doubled between 1990 and 2000 and are expected to account for one seventh of total health care costs by 2012 [see Table 1].²⁰ Moreover, whereas consumers pay less than 3% of hospital service costs out of their own pockets, they pay about 32% of pharmaceutical costs.

One of the factors contributing to these increased costs is the presence of legal restrictions, in the form of patents afforded to pharmaceuticals and medical devices that prevent other firms from entering the market with a similar product. Patents give pharmaceutical companies and device manufacturers legal monopolies for a period of 20 years. The purpose of this law, as expressed in Article 1, Section 8 of the US Constitution, is "to promote the progress of science and the useful arts by securing for limited times to inventors the exclusive right to their respective discoveries." In addition, at the end of the patent period, pharmaceutical companies can switch their products from prescription to over-the-counter status and gain 3 additional years of market exclusivity if they can demonstrate that any misuse of a drug will not endanger a consumer's health. During these protected periods, companies work to establish brand loyalty among physicians and consumers.

Pharmaceutical companies and device manufacturers argue that the costs of research, development, and testing would be impossible to recoup without these legal

Table 1 Major Components of Health Spending, 1999–2009

	1990	1993	1997	2000	2003	2006	2009
Hospital care	9.6	8.0	3.6	5.6	7.5	7.0	5.1
Physician and clinical services	12.8	8.5	4.6	7.0	8.5	5.9	4.0
Prescription drugs	12.8	8.2	11.1	15.3	10.5	8.5	5.3

Adapted from Martin A et al.³⁸

protections. Others, however, are concerned that companies are using their monopoly power to raise prices, restrict output, and earn excessive profits. Since 1980, the rate of growth in drug prices has exceeded consumer price inflation rates. In addition, the profitability of drug firms has been consistently higher than that of the manufacturing industry average.²¹

Again, pharmaceutical companies argue that the high rate of profit observed in the industry is justified by the significant risk and cost of innovations. However, not all innovations are costly to the company, risky to investors, or beneficial to society. One of the most notable examples of profiteering by a pharmaceutical company was the introduction of the “new little purple pill.” The original purple pill, Prilosec (a trade name for omeprazole), was introduced in 1989 by AstraZeneca. In 2000, it was the best-selling drug in the world, with over \$6 billion in sales per year. When the patent was due to expire in 2001, the company applied for a patent for the “new little purple pill,” Nexium (esomeprazole magnesium), which was simply a chemical isomer of Prilosec. Despite the Food and Drug Administration’s determination that Nexium offered no significant clinical advance over Prilosec, a patent was awarded. The company launched a very successful marketing campaign, and in 2006, sales of Nexium exceeded \$5 billion. The price of Prilosec for consumers is \$30 per month, whereas that of Nexium is \$200 per month. The current market-based model of new product development accompanied by long periods of monopoly protection can be predicted to increase the costs of health care substantially.

PRICE TRANSPARENCY

For most goods and services, price transparency leads to lower and more uniform prices, a view consistent with standard economic theory. Currently, there is considerable variation in prices for similar procedures. For example, a comprehensive metabolic panel costs \$97 at San Francisco General Hospital and \$1,733 at Doctors Hospital in Modesto, California. A single Percocet tablet costs \$6.68 at San Francisco General, \$15.00 at UC Davis in Sacramento, and \$35.50 at Doctors Hospital in Modesto.²² If evidence from other markets could be applied to health care, then reforms that increase transparency should result in lower and more uniform prices.^{23,24} However, there are reasons to be concerned that greater price transparency would not have the desired effect. Health care differs from other consumer goods in ways that make it difficult to apply empirical evidence from other markets. For one, patients with insurance pay little of the cost of their medical care and are therefore less price sensitive. In addition, there is evidence to suggest that price acts as a proxy for quality in health care, with many believing that higher-cost care is better care.²⁵ Second, physicians typically make choices for patients, such as what tests to order, whether and where to hospitalize, and which specialists to recommend. Patients are unlikely to challenge this advice to save a few dollars. Finally, transparency could create an incentive to raise prices. Hospitals that charge different payer types different prices would be inclined to publish the higher price. For these reasons, pricing may have a more muted effect on the health care market than

it has on other markets, and improvements in price transparency may be less effective. So far, preliminary data from New Hampshire²⁶ and California²² suggest that this is the case. Neither state demonstrated any effect of hospital price transparency 2 years after initiation.

ADMINISTRATIVE COSTS

In general economic terms, markets function best and society benefits most when multiple suppliers compete to produce the highest-quality product at the lowest cost. With health care, however, this process has resulted in a bewildering array of insurers and contracts. Virtually every physician in the United States has had to expend considerable time and effort dealing with complicated, arcane, and apparently deliberately confusing rules and requirements.

The repeal in 1986 of laws that sought to regulate the growth of the health care industry resulted in an abandonment of all efforts to constrain market-based entrepreneurship in health care. Not-for-profit hospitals and health maintenance organizations converted to for-profit status. Consolidation of the insurance industry reduced the number of plans available in a market area, thus affording insurers monopoly power and leading to higher prices. The cost of administering private health insurance in the United States reached \$143 billion in 2005.²⁷ For-profit insurance companies have reaped impressive profits and gains in stock value, as well as significant political power.

As a reaction to this state of affairs, some critics of the US system have asserted that the adoption of a simplified, Canadian-style, single-payer health insurance system would yield large savings in administrative costs, which could then be used to expand coverage to those who are currently uninsured. A 2003 study compared administrative health care costs in the United States with those in Canada.²⁸ In 1999, per capita health administration costs amounted to \$1,059 in the United States (for a total cost of \$294 billion), in contrast to \$307 in Canada [see Table 2]. The authors arrived at these figures by analyzing data from governments, hospitals, insurance companies, and physicians. They argued that much of the difference between the two countries was accounted for by the multiple sources of health coverage in the United States, as opposed to the single source in the Canadian system. This analysis has not been replicated by others, and an accompanying editorial questioned the methodology used.²⁹ Nevertheless, the author of the editorial did agree that the current system is “an administrative monstrosity, a truly bizarre mélange of thousands of payers with payment systems that differ for no socially beneficial reason.”

THE PATIENT PROTECTION AND AFFORDABLE CARE ACT AND OTHER LEGISLATIVE INITIATIVES

The most significant impact of the Patient Protection and Affordable Care Act (ACA) is that an estimated 32 million Americans will gain insurance coverage by 2019. The health reform law mandates that currently uninsured Americans obtain health insurance. Medicaid eligibility is expanded and substantial subsidies are provided to make insurance more affordable for those ineligible for public insurance programs. Currently, the uninsured rely heavily on the safety-net health care system, which is associated with

Table 2 Administrative Costs of Health Care: United States versus Canada

Administrative Cost Category	United States		Canada	
	Total Cost (\$ billion)	Per Capita Cost (\$)	Total Cost (\$ billion)	Per Capita Cost (\$)
Insurance overhead	72	259	1.43	47
Employer costs	15.9	57	0.257	8
Hospital administration	87.6	315	3.1	103
Practitioners	89.9	324	3.3	107
Total	294.3	1,059	9	307

higher costs and poorer health outcomes. If previous trends hold, the newly insured will enjoy better health outcomes, but the cost implications of health care reform are less clear.

Both the Centers for Medicaid & Medicare Services (CMS) and the CBO have projected that health care reform will result in an expansion of national health care expenditures.^{30,31} The ACA includes a number of mechanisms to offset the new spending, including a reduction in the update factor for Medicare hospital reimbursement, a reduction in the overpayment to Medicare Advantage insurers, an assessment on employers whose employees use subsidies rather than employer-sponsored insurance, and an increase in the Medicare tax for high-income families. The CBO estimates that the revenue increases will exceed the increased costs and ultimately reduce the federal deficit by more than \$100 billion in the first decade and more than \$1 trillion in the second decade.²² However, critics argue that although these measures may pay for health care reform, they do nothing to rein in the growth of health care costs. Health care spending in the United States already accounts for 17% of GDP. At the current rate of growth, it will reach 38% of GDP by 2075. The ACA includes a variety of provisions intended to lower the rate of cost growth (bend the health care cost curve), including physician payment reform, incentives to coordinate care for patients with chronic conditions, increased access to electronic health records, and funding for comparative effectiveness research, but there is currently little evidence that any of these measures actually work.

A second implication of increased access to health insurance is the need for a larger primary care workforce. Numerous studies have demonstrated that access to primary care is associated with improved outcomes at reduced cost. Although primary care physicians provide 57% of all patient visits, they represent only 35% of the US physician workforce.³² Even without the new demands created by health care reform, the aging of the population and the increasing proportion of the population with a chronic medical condition have strained the capacity of the primary care workforce. The 2008 Medicare Payment Advisory Commission (MedPAC) beneficiary survey found that 28% of beneficiaries without a primary care physician reported a problem finding one.³³ This represented a 17% increase from 2006. The number of beneficiaries reporting a problem finding a new specialist declined. The Massachusetts experience with expanded health insurance coverage illustrates the disconnection between access to health insurance and access to care. The average wait time for a new patient to obtain an

appointment to see an internist in Massachusetts was 31 days in 2008, up from 17 days in 2005.³⁴ Patients without access to primary care will be forced to continue to seek care at high-cost, poor-continuity sites, such as emergency departments. General surgery also faces shortages that are likely to be exacerbated by health care reform. The overall number of general surgeons has declined by 26% over the past 25 years.³⁵ Rural areas are most acutely affected. The income gap between generalist and subspecialist careers and rising medical student debt account for most of the decline in medical student interest in both of these generalist careers.

The ACA and the American Recovery and Reinvestment Act of 2009 include several provisions aimed at highlighting the importance of primary care and general surgery. The economic stimulus package provided about \$500 million for training programs in health professions, including \$300 million for expanding the National Health Service Corps, a program that offers scholarships and loan repayment for health professionals who agree to serve in shortage areas for 2 to 5 years. The ACA includes additional funding to support training of primary care providers, redistributes approximately 900 unfilled residency positions into primary care and general surgery, provides a 10% bonus under the Medicare fee schedule for primary care providers, and requires that states increase Medicaid payment to Medicare rates for primary care services. Notably missing in the provisions is a lifting of the cap on the total number of residency positions, which were frozen by the Balanced Budget Amendment of 1997. In the absence of an expansion of total residency training positions, it is not clear that the provisions will make a significant dent in the projected primary care and general surgery shortages.

Implications for Surgeons

Market-based health care has not only increased the costs of care but has also changed the professional behavior of physicians. Organized medicine's priorities place the financial interests of physicians above access to and quality of care. Hospitals invest in programs that promise a high return on investment with less regard for evidence of benefit or greater societal need. The fragmentation of the profession into over 130 specialties and subspecialties has resulted in competition among disciplines, further promoting self-interest over best practices. In this environment and despite advances in evidence-based medicine, individual physicians are equally tempted to place their own interests above those

of patients by recommending interventions of limited value. A 2007 study highlighted these disturbing trends by revealing that median wait times for both routine and urgent dermatology appointments were nearly four times longer than wait times for an appointment to receive cosmetic botulinum toxin injections.³⁶ Patients with a potentially cancerous skin lesion wait a median of 26 days to be seen by a dermatologist.

Adam Smith's 1776 book *An Inquiry into the Nature and Causes of the Wealth of Nations* is considered the first full-scale treatise in classical economics. In it, Smith espoused the virtues of the market as a means toward national wealth. He made the case that self-interest leads naturally to greater public good: "It is not from the benevolence of the butcher, the brewer, or the baker, that we expect our dinner, but from their regard for their own interest. We address ourselves, not to their humanity, but to their self-love and never talk to them of our own necessities but to their advantages."³⁷ However, Smith was also quick to draw a distinction between self-interest and greed. He criticized those who desired excessive wealth, for whom "the chief enjoyment of riches consists in the parade of riches, which in their eyes is never so complete as when they appear to possess those decisive marks of opulence which nobody can possess but themselves." In his view, the market's ability to foster the growth of a nation depended on social cooperation, discipline, and respect for others. Greed denied others and thereby weakened the whole.

Finally, Smith understood the intrinsic failure of the market to ensure equity and the vital role of government in this regard:

Is this improvement in the circumstances of the lower ranks of the people to be regarded as an advantage or as an inconvenience to the society? The answer seems at first sight abundantly plain. Servants, labourers, and workmen of different kinds, make up the far greater part of every great political society. But what improves the circumstances of the greater part can never be regarded as an inconvenience to the whole. No society can surely be flourishing and happy, of which the far greater part of the members are poor and miserable. It is but equity, besides, that they who feed, clothe, and lodge the whole body of the people, should have such a share of the produce of their own labour as to be themselves tolerably well fed, clothed, and lodged.³⁷

Arguably, health care is as necessary to the prosperity of a society as food and lodging are.

Although individual physicians can do little to fix the society-wide problems created by market-based health care, surgeons can help restore confidence in the profession by helping to develop and then adhering to evidence-based approaches to surgical intervention. Communication skills and attention to the needs of patients should be stressed as vital to the best patient care. Equally important is remembering that the profession of medicine is not merely another way of making a living. The importance of education in evidence-based and compassionate care, preferably one on one, for the training of surgical residents and students must also be emphasized. Mastery of these skills, which place patient interests ahead of surgeon interests, truly defines professionalism.

Financial Disclosures: None Reported

9 MINIMIZING VULNERABILITY TO MALPRACTICE CLAIMS

*William R. Berry, MD, MPH, FACS**

No surgeon wants to be sued. The threat of a medical malpractice suit is, however, a reality for everyone who practices surgery. Lawsuits can extract a tremendous price from those who are sued. The surgeon who has been sued bears the burden of the lawsuit for a period of years while it slowly works its way through a system that is not designed for speed or efficiency. Life decisions are often postponed. Sometimes careers are forever changed. Confidence is shaken, and sleep is lost. For some, there is no relief until it is over; for others, it repeatedly intrudes on life. It is better to never be sued. The situation, however, is not totally out of the surgeon's control—nor is it hopeless. Armed with knowledge of the legal system and an understanding of why patients seek the courts, the surgeon can decrease the likelihood of ever being named. This chapter provides strategies for avoiding lawsuits and advice for dealing with a suit if one is ever filed against you.

What Is Medical Malpractice?

Medical malpractice law is a subset of the law of torts or law that concerns itself with civil injuries as a result of negligent behavior or a failure to practice due diligence. For a medical malpractice suit to be successful, a number of elements must be satisfied. A plaintiff (the patient or the patient's estate) must prove, by a preponderance of the evidence, that the defendant (the surgeon) was negligent or failed to exercise due care in the circumstances. A plaintiff must also show that the defendant's negligence caused his injuries and that he has suffered injuries or quantifiable damages as a result.

Four conditions must be met:

1. There must be a "relationship" of some kind between the patient and the surgeon. The relationship can be a direct one, in which the surgeon operated on the patient, or a more indirect one, in which the surgeon only consulted.
2. The surgeon must be "negligent," which means that he or she did not perform to the "standard of care." The definition of the standard of care varies from state to state but usually means that the surgeon failed to perform in a manner consistent with the care that would be given by the average physician practicing in the same specialty. To help the judge and the jury understand the evidence in relation

to the standard of care, both sides use "expert" witnesses to provide opinions about the care.

3. The surgeon's negligence must have been the cause of the injuries that the patient sustained.
4. The injuries that the patient has suffered must have caused measurable damage. This reflects the civil nature of malpractice, whereby injuries are compensated with a payment.

The judge and/or the jury are responsible for determining whether each of these conditions has been met and uses a standard of "more likely than not." Unlike criminal law, the evidence does not have to reach the level of "beyond a reasonable doubt"—only that there is a greater than 50% chance that the conditions were met. In our judicial system, the judge and the jury interpret and decide whether the "standard of care" was met.

Malpractice lawsuits often begin with the filing of suit papers that are delivered or "served" to those being sued. A written demand for compensation for an injury from the patient or an attorney is usually called a claim and can precede the filing of a suit. Suits and claims can end in different ways, and not all involve a jury trial. They can be dropped by the patient at any time; denied by the insurance carrier and not pursued by the patient; settled with a payment before, during, or after a trial; dismissed by the court; or ended with a jury verdict.

Personal Issues for the Defendant Physician

How physicians cope personally with being a defendant in a medical malpractice suit varies, but a number of factors come to bear on the amount of stress that litigation inflicts. These factors include the physician's previous exposure to litigation claims, degree of familiarity with the legal system and the litigation process, and previous experience testifying in the courtroom or in depositions; the size of the claim as measured by the seriousness of the alleged injury; and the presence or absence of a claim for punitive damages—which, of course, are not insured by professional liability policies. Some physicians experience a sense of profound isolation when they are first named in a suit, particularly when service of suit papers is accompanied by the standard instruction from their risk management office or legal counsel not to discuss the case with anyone.

Allegations of negligence or substandard care, in and of themselves, are bitter pills to swallow, but they are all the more painful when they are accompanied with a claim for punitive damages. Such claims, announced in the formal complaint, are then typically followed promptly with a grim

* The author and editors gratefully acknowledge the contributions of the previous authors, Grant H. Fleming Esq and Wiley W. Souba, MD, ScD, FACS, to the development and writing of this chapter.

letter to the defendant physician from the insurers involved, reminding the physician that there is no coverage for punitive damages awarded. The allegations in the plaintiff's complaint necessary to support a claim for punitive damages are hurtful and sometimes outrageous; the physician is accused of willful, reckless, and wanton behavior bordering on intent to injure the plaintiff. The awards sought in such cases reach far beyond fair compensation for the injured plaintiff. Rather, punitive damages are calculated to punish the defendant physician—the perceived wrongdoer—and to serve as public sanctions. The physician against whom punitive damages are sought then undergoes pretrial discovery, sometimes shortly after suit is filed. This process involves requests (interrogatories) for detailed accounting of personal assets that might be available to be attached in the event of a judgment in the plaintiff's favor.

Whether or not punitive damages are sought, it is difficult for most physicians to regard being harpooned by a medical malpractice claim as merely a cost of doing business, and for many, the arduous and seemingly never-ending nature of the claim is distracting and potentially debilitating.

Who Brings Medical Malpractice Claims?

Brennan and colleagues have shown that there is no relation between the occurrence of adverse events and the assertion of claims, nor is there any association between adverse events and negligent or substandard care.¹ These authors did, however, find a relation between the degree of disability and the payment of claims. They found that patients who were injured through negligent care usually did not file suit and that the patients who did file suit often did not suffer from negligent care. Further, they also found that patients do turn to the courts when they are disabled in the course of medical care. The need to pay for long term care for themselves or a dependent often contributes to the filing of the suit.

Only a small fraction of patients who are injured through substandard care or treatment actually bring claims or suits.² Localio and colleagues concluded that although 1% of hospitalized patients sustain a significant injury as a result of negligent care, fewer than 2% of these patients initiate a malpractice claim.³ Other authors have found that only 2 to 4% of patients injured through negligence file claims, yet five to six times as many patients who sustained injuries that do not meet the threshold for malpractice also file malpractice claims.⁴

Strategies for Preventing Malpractice Suits

Clearly, not every malpractice suit can be prevented. When catastrophic injuries follow surgery or treatment, the emotional impact of the tragedy, coupled with overwhelming economic pressures, can create an environment in which a claim is likely. On the other hand, not all adverse outcomes from treatment result in claims. Why is it that some patients and families sue for adverse outcomes and some do not? Why do some patients sue for adverse outcomes that are expected and that occur in the context of high-quality care? The answers to those questions typically have to do with physician-patient relationships rather than professional skill.

It has become increasingly clear that surgeons can reduce the likelihood of litigation by adopting a few key habits and practices with their patients and their patients' families. These include building trust through open communication, making effective use of the informed consent process, keeping accurate and complete medical records, and educating office staff.

COMMUNICATION AND INTERPERSONAL SKILLS IN THE PHYSICIAN-PATIENT RELATIONSHIP

Although advancing medical technology has elevated patients' level of expectation regarding treatment outcome, easy public access to medical information on the Internet has encouraged patients to become partners with their physicians in their own care. Experience with juries over the past few decades continues to support the belief that, in general, laypersons have a high regard for physicians and a deep respect for their superior level of knowledge and training. At the same time, patients expect and deserve to receive thorough understandable explanations from their physicians regarding their diagnosis, their treatment plan, and the risks and benefits of their treatment. Even when the disease process is beyond the physician's control, the physician can create an environment for effective communication with the patient. Years of listening to patients and their family members relate their experiences at depositions and trials have confirmed that the quality of communication and the presence of trust between physician and patient are the most important factors in the patient's decision to file a medical malpractice suit.

Several researchers have analyzed physician-patient communication and its relation to claims for damages for alleged professional negligence. Beckman and colleagues studied 45 deposition transcripts of plaintiffs in settled malpractice suits, focusing on the question of why these plaintiffs decided to bring malpractice actions.⁵ They concluded that the process of care, rather than the adverse outcome, determined the decision to bring the claim. They found that 71% of the depositions revealed problems with physician-patient communication in four major categories: (1) perceived unavailability ("You never knew where the doctor was," "You asked for a doctor and no one came," "No one returned our calls"); (2) devaluing of the patient's or the family's views (e.g., perceived insensitivity to cultural or socioeconomic differences); (3) poor delivery of medical information (e.g., lack of informed consent, failure to keep patients informed during care, or failure to explain why a complication occurred); and (4) failure to understand the patient's perspective.

Vincent and colleagues examined the reasons patients and their relatives take legal action in a survey of 227 patients and relatives.⁶ Over 70% of respondents were seriously affected by incidents that gave rise to litigation. However, the decision to take legal action was determined not only by the original injury but also by insensitive handling and poor communication after the original incident. Patients taking legal action wanted greater honesty, an appreciation of the severity of the trauma they had suffered, and assurances that lessons had been learned from their experiences.

Levinson and colleagues studied specific communication behaviors associated with malpractice history.⁷ Although they did not discover a relation between those two factors in the

surgeons they studied, they found that primary care physicians who had no claims filed against them used more statements of orientation (i.e., they educated patients about what to expect), used humor more with their patients, and employed communication techniques designed to solicit their patients' level of understanding and opinions (i.e., they encouraged patients to provide verbal feedback).

Hickson and colleagues studied specific factors that led patients to file malpractice claims after perinatal injuries by surveying patients whose claims had been closed after litigation.⁸ Dissatisfaction with physician-patient communication was a significant factor: 13% of the sample believed that their physicians would not listen, 32% felt that their physicians did not talk openly, 48% believed that their physicians had deliberately misled them, and 70% indicated that their physicians had not warned them about long-term developmental problems.

The American College of Surgeons' Patient Safety and Professional Liability Committee performed a closed claims study of 460 liability claims between April 2004 and February 2006.⁹ Ninety of the claims (19.8%) were filed because of failures in communication that predominantly involved patients or their families. Among some of the claims, the standard of care was clearly met. However, defendants suffered litigation solely because they failed to spend the time required to provide the insight and satisfaction necessary to defuse anger and mistrust.

Many defense attorneys recount stories of surgeons who had developed a positive rapport with their patients and were not named in a suit, whereas other physicians involved in the patient's care were named. Patients apparently made these decisions without regard to the extent of each defendant's factual involvement in the case but instead sued physicians with whom they had poor or weak relationships. A component of the motivation to sue may be simply an unsatisfactory or incomplete explanation of how and why an adverse outcome occurred. Patients who remain uninformed often assume the worst: that their physician is uncomfortable talking about the complication because he or she made a mistake, was careless, or is hiding something. Malpractice plaintiffs have sometimes claimed that when they sat through the process of jury education during the trial, it was the first time they received any explanation of the complication for which they had brought suit. Physicians should make a point of explaining to patients and their families how and why adverse conditions arose, independent of any possible deficiencies in the quality of care received at home or in patient compliance. Patients and their families are keenly sensitive to unintended inferences that blame for the bad outcome rests with them.

The principles of good communication are the same, whether or not an adverse event has occurred. They include the following:

1. *Educating and informing the patient.* Convey medical information in descriptive terms that patients can understand, using illustrations, sketches, and diagrams. Ask about the response to the therapeutic regimen. Provide counseling and instruction if no improvement is observed. Inform the patient about specific steps in the examination or treatment plan.

2. *Ensuring patient understanding.* Ask patients whether they understand what they have been told; check the understanding by listening to the patient after providing an explanation. Demonstrate respect for any cultural or socioeconomic differences that may be impeding the patient's understanding.
3. *Emotionally engaging the patient.* Demonstrate concern and understanding of the patient's complaints. Express empathy; use humor where appropriate. Demonstrate awareness of the patient's occupation, social circumstances, hobbies, or interests.
4. *Following up with the patient.* Return telephone calls. Explain the protocol for substitute or resident coverage and introduce patients to other personnel who may be following their care. During longer hospitalizations, keep the patient and the family informed of the patient's progress or treatment plan. Keep the referring physician promptly informed by providing treatment or discharge summaries. In the event of a patient's death, meet with the family several weeks later to review and explain autopsy findings and answer questions that they might have about what happened to their loved one.

Further guidelines apply when an adverse outcome occurs. In the hospital setting, prompt disclosure of an untoward or unexpected event that causes injury or harm is mandated by the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO). JCAHO standards require disclosure of unanticipated outcomes "whenever those outcomes differ significantly from the anticipated outcome."¹⁰ The responsibility to communicate lies with both the attending physician and, in the case of a complication incident to surgery, the person accountable for securing consent for the procedure.

When possible, it may be advisable to invite other responsible caregivers to take part in the discussion of the adverse event with the patient and the family. Consideration should also be given to inviting other persons who may be sources of support for the patient and could benefit from the disclosure. During the discussion, express regret for the occurrence, without ascribing blame, fault, or neglect to oneself or any other caregiver. Describe the decisions that led to the adverse event, including those in which the patient participated. Explain and outline the course of events, using factual, nontechnical language, without admitting fault or liability or ascribing blame to anyone else. Do not speculate or hypothesize. State the nature of the mistake or error, if one was made, and highlight the expected consequences and prognosis, if known. Outline the plan of corrective action with respect to the patient. In the event that certain information is unknown at the time of the discussion (e.g., the etiology of the condition, suspected equipment malfunction in the absence of controlled testing, or pending laboratory test results), tell the patient and family that such information is currently unknown and offer to share the information with them when it becomes available.

A special case exists when children suffer injuries. Parents may seek subconsciously to avoid blaming themselves and so may attempt to transfer the responsibility to the health care providers. After a complication or adverse event arises in a pediatric case, the physician should speak openly with the

parents. The discussion should cover possible or known causes or mechanisms of the injury or death that are independent of any care rendered by the parents, including prenatal care or home care of a chronically ill child.

THE INFORMED CONSENT PROCESS

Effective informed consent can reduce the risk of litigation. The informed consent process is an extension of good communication practices, albeit one that is mandated by law. The tort of informed consent is derived from the concept of battery—for example, unauthorized touching. Patients are deemed not to have consented to a procedure unless they have been advised of all the risks involved in it and all the alternatives to it. Although differing somewhat from state to state, in most jurisdictions, the standard is objective rather than subjective. In other words, the risks and alternatives that must be disclosed are those that a “reasonable patient, in similar circumstances”—not necessarily the plaintiff—would regard as material to the decision whether to undergo the surgery in question. With procedures for which the statistical incidence of risks has been published or is known, the physician has a duty to quantify for the patient the likelihood of the risk being realized. If the patient’s particular condition or situation is such that the likelihood of the risk occurring is higher than average, the physician has the duty to so inform the patient.

Many physicians ignore another critical element in the required informed consent discussions: describing the range of reasonable alternative procedures or modalities other than the procedure in question that are available to the patient. The hazard that such omissions entail is illustrated by a case in which the physician performed a transesophageal balloon dilatation of the esophagus to address achalasia that had not responded to conservative medical therapy. The risk of esophageal perforation was disclosed as part of informed consent, and the procedure was performed totally within the standard of care, but the patient suffered perforation of the esophagus with serious permanent and long-term disability. Although an alternative approach, via thoracotomy, was a known option, it was not used at the defendant hospital, and the informed consent discussion therefore did not include the surgical alternative. The defendants were forced to settle the case for a significant amount of money, even though there had been no negligence and the patient acknowledged that the risk of esophageal perforation had been thoroughly disclosed. A breach of informed consent was easily established because one of the reasonable alternatives was not disclosed to the patient. The argument that a reasonable person would probably have rejected the surgical alternative had it been disclosed was not a valid defense; nondisclosure of a reasonable alternative, in and of itself, created strict liability.

Some surgeons regard the informed consent discussion as an inconvenient imposition on their time. However, the few minutes needed for this discussion pale in comparison with the time needed to defend a lawsuit involving a breach of informed consent, either as the central claim or as an ancillary one. In addition, given that the surgeon’s personal interaction with a patient may be significantly limited in comparison with that of the primary care physician, obstetrician, gynecologist, or medical specialist, the informed consent

discussion presents an important opportunity for the surgeon to develop a rapport and a positive relationship with the patient. Such a rapport can be invaluable in the event of a later complication or adverse outcome. An effective informed consent discussion may reduce the likelihood of a claim for a particular adverse outcome if the patient remembers that the risk of its occurrence was disclosed and discussed.

Informed consent is not the consent form; it is the process of informing the patient. The form is merely a piece of evidence documenting that informed consent occurred; the critical factor is the content of the discussion. For the form to be effective, it must cogently summarize the discussion in a manner that makes it difficult for the patient later to refute, in a “he said, she said” controversy, the version of the discussion that the physician may be rendering in the courtroom under oath.

An effective discussion of informed consent based on custom and habit is essential because of the slow pace of the legal system. In most jurisdictions, the statute of limitations for bringing claims involving adult patients is 2 years. By the time the defendant physician’s pretrial deposition is taken, another 1 to 3 years may have elapsed, and after that, even more time passes before the conversation will have to be relayed under oath if the claim goes to trial. It is exceedingly rare that physicians can actually recall the informed consent discussion in question at the time of the suit. However, the content of the communication can be proved more reliably through custom and habit than through direct recollection, particularly when the elements of the discussion are corroborated with a comprehensive and clear form signed by the patient.

In some cases, physicians encourage the showing of a patient education video that explains the intended procedure; such a video should also communicate the risks of the procedure. The use of educational videos can provide additional evidence to support the defense that the patient gave informed consent. Each version of the video should be labeled with the dates when it was routinely used and should not be discarded when it is replaced with updated versions. The patient’s chart should reflect that the patient watched the video and had no questions after a review of its contents.

The physician who will perform the procedure, not the nurse or resident who will assist at it, has the duty to secure the patient’s consent. However, information provided by other health care providers can be used by the defense as evidence.

DOCUMENTATION

Along with effective communication techniques and informed consent protocols, good documentation practices can minimize a surgeon’s risk of becoming a defendant in a medical malpractice suit, or at least provide a more effective defense if litigation is commenced. Although the purpose of keeping medical records is to provide subsequent caregivers with important information relevant to the patient’s condition and treatment, in the context of litigation, medical records are used to demonstrate what care was or was not rendered. A standard question that plaintiffs’ attorneys ask defendants at pretrial depositions is whether the defendant agrees with the adage, “If it is not documented, it wasn’t done.” Time and time again, otherwise defensible cases are compromised

because of inadequate documentation, such as failure to document an order, the time an order was given, a critical telephone call from the patient or patient's family, a critical informal consultation, or critical symptoms reported by a patient during the course of an examination or clinic visit.

Various tort provisions have been enacted with the intention of upgrading the quality of expert witnesses in some states. Better qualified witnesses will generally be more objective, authoritative, and credible than less well-qualified witnesses. Such witnesses may nonetheless be influenced, sometimes to the defendant physician's detriment, by the quality of the documentation provided. On the one hand, if the chart is well documented and the case is defensible, many reputable experts will be loath to give an opinion stating that substandard care was provided. On the other hand, absence of adequate documentation sometimes prejudices expert case reviewers in favor of the plaintiff, even though subsequent deposition testimony may provide a cogent and defensible explanation for how and why the adverse event or complication occurred.

It is crucial to ensure that telephone conversations are documented. Cases have been saved in the courtroom simply because a resident who received a call jotted a short note of the patient's complaint and the advice given and pasted it in the patient's chart. All appointments, cancellations of appointments, and reasons for cancellations should be logged. If printed images of bedside ultrasound scans are relevant, the printed copy should be stapled and placed into the progress notes of the patient's chart. If the surgeon provided the patient with a sketch to help explain an operative procedure, the sketch should be placed in the patient's chart, with the date written on it. In one case involving an informed consent issue, the defense was able to produce a sketch of the operation that the surgeon had made on the reverse side of a laboratory report in the patient's chart, thereby refuting the patient's contention that no explanation of the procedure had ever been given. If equipment malfunction was involved in an adverse outcome, such as a death in which a postmortem examination was conducted, the surgeon should insist that the risk management office provide a secure place to store the specimen or equipment in question for later testing or use as a trial exhibit. If an anomalous condition contributed to an adverse outcome in a fatal case, efforts should be made to ensure that the pathologist at least photographs the abnormality at the time of the autopsy if the specimen is not to be preserved for later use.

Whenever an untoward outcome or event occurs, the event should be documented in the chart in a purely factual manner, without resort to expressions of opinion or suggestions that other health care providers are to blame. If additional relevant information subsequently becomes available, it can be helpful to make a late entry in the chart, with the time of the entry appropriately documented. Be cautious of using self-serving language in notes that are dictated or recorded after complications have occurred, that is, the "late" operative report that explains how "carefully" the surgeon operated to avoid complications.

If one realizes that an error in documentation has been made in the patient's chart (e.g., inaccurate information is recorded), it is vital not to remove the page and start over and not to scratch out, write over, or "white out" the mistake.

The appropriate way of handling such an error is to draw a single line through the inaccurate information, record the correct information, and initial and date the amendment. Clearly, a medical record should never be altered in an attempt to cover up something. In the event of a suit, this act could lead to the loss of an otherwise defensible case.

The following are guidelines for documentation:

1. Time and date your notes.
2. Write legibly.
3. Record the information that is important to subsequent caregivers. When an unusual treatment course is planned, include a clear explanation.
4. Record pertinent negative findings.
5. Do not criticize colleagues in your notes. The record is not a place to settle disputes.

EDUCATING AND INFORMING OFFICE STAFF

More than ever before, every practicing surgeon must recognize that his or her office staff must also be well informed and well educated about malpractice issues. In-service training of office staff is pivotal to reducing the risk of being sued. All office personnel should be well informed and educated on issues of confidentiality, including how to answer the telephone, what kinds of conversations are inappropriate, and the dissemination of medical information. It is also critical to maintain good relationships with patients; many avoidable lawsuits have arisen simply because a member of the physician's office staff was rude to a patient on the telephone or because the patient waited too long to see the doctor without an explanation. Whenever patients or family members call or write to express displeasure with service they received—whether that service was provided by the surgeon, the resident, the clinic staff, or the nursing team—courtesy and common sense decree that the dissatisfied customers should be contacted and allowed to vocalize their complaints, either over the telephone or in person. Willingness to listen to these persons indicates a genuine interest in improving the delivery of patient care and may well prevent some claims.

ADDITIONAL STRATEGIES

In the current malpractice climate, it is important to be vigilant for patients who tend to be inordinately dissatisfied, to complain unreasonably, or to exhibit rudeness. Such patients should receive the same high-quality medical care as any other patient, but extra attention should be paid to documentation of missed appointments, telephone instructions given, and the informed consent process. Paranoia is neither necessary nor helpful in dealing with these patients, but care should be taken to inform the staff of any concerns. Litigious patients may feel short-changed by the medical system because of past adverse experience with the medical delivery system or economic pressures exacerbated by the expense of testing and treatment, and when they are not given satisfactory explanations for a poor outcome or a therapeutic failure, they may seek to elicit derogatory statements about another physician's advice or treatment. Accordingly, whereas dialogue and open discussion of adverse outcomes with patients are essential, it is important to steer clear of criticizing another physician or health care provider. The proper forum for constructive criticism of other health care professionals with a view toward improvement is the peer

review system, not a discussion with the patient or the patient's family. If the critique is made in the context of peer review, the proceedings are shielded from discovery in litigation.

If you receive a complaint from a patient about his or her care, it should be responded to promptly and respectfully. If the patient was hospitalized, turning to the hospital's patient representatives for guidance can be helpful. You should investigate the complaint and communicate in a clear and sympathetic manner your findings. Make certain that you follow through. Although not every patient can be satisfied in this way, even minor complaints can escalate into lawsuits if they are ignored.

With the enormous attention currently focused on minimizing health care expenditures, virtually all surgeons feel pressured to shorten the duration of hospitalization and decrease the use of diagnostic tests and medications. Such feelings, although completely understandable, should never be allowed to influence patient care decisions. Juries persuaded that treatment was withheld or delayed because of a lack of medical insurance have been known to award substantial punitive damages. In cases where denial of coverage by the health care plan is a particular problem, it can often be helpful to talk directly with the medical director of the health plan.

What Should Surgeons Do If Sued or If Threatened with a Suit?

If you receive notice that a patient intends to file a suit or has actually filed a suit, you should immediately notify your insurance carrier and follow its advice. Every state has unique standards and procedures that must be followed in response to suits and claims that the insurance carrier can help you with. Most carriers have representatives who will handle the claim or suit and most often will arrange for you to have defense counsel appointed for you. Do not respond to a lawyer representing a previous patient in a potential claim or suit without first contacting your insurance carrier or defense counsel. If the patient is currently under your care and wishes to continue to have you care for him or her and you feel comfortable continuing to care for the patient, you can usually continue to provide care. However, it is also appropriate to arrange for referral to another surgeon if necessary. However, you should never speak directly to the patient about the claim or suit if you continue to provide care. If you receive proper written authorization from the patient or his or her attorney, you should honor the request and provide a complete copy of the record to them. If you suspect that the records are being requested because of a potential malpractice claim, you should notify your insurance carrier.

MEASURES FOR ASSISTING IN THE DEFENSE

First, all relevant records, telephone logs and messages, and e-mail correspondence or other notes should be assembled, and every effort should be made to cooperate fully with the claims representative of the insurer and the representative of the hospital risk management team if the hospital is involved in the case. Under no circumstances should any records be altered, amended, or discarded when a suit is initiated. The facts of the case should not be discussed with

any colleagues until legal counsel has become involved because anyone who takes part in such discussions may be asked to repeat the substance of the conversation at the time of pretrial depositions. The available records should be reviewed and a confidential summary of the case prepared; this summary should be addressed only to legal counsel, with no copies to anyone. If the media are involved at the outset of the suit, under no circumstances should defendants attempt to be spokespersons on their own behalf; this task should be left to others who are better equipped to determine how much information to provide to the media about the controversy.

It is advisable to find out the name of the defense lawyer assigned to the case and arrange an initial meeting to familiarize him or her with the relevant medical issues. Any medical research done to assist the defendant and legal counsel with the issues should be carried out with the understanding that the research is performed in the context of communication with counsel: all independent research that is conducted for the defendant's own edification, rather than for communication with counsel, is discoverable by the plaintiff. It is vital to take whatever time is necessary to educate the defense attorney on the medical issues involved so that the attorney can then gather more information effectively. The defendant can recommend and discuss with counsel certain fact-gathering tasks to be done by counsel on the defendant's behalf. Both defendant and counsel can begin thinking about whom to engage as an outside expert to assist in identifying weak points or issues in the case before the defendant submits to a deposition by the plaintiff's lawyer. Once defendant and counsel have agreed on an expert, however, only counsel should approach or contact the expert.

SETTLING THE CLAIM VERSUS TRYING THE CASE

Although many professional liability policies require the consent of the insured before a settlement offer can be made, it still is usually possible for the insurer to settle the claim over the objection of the insured physician after review and consideration of the objecting physician's argument against settlement. Nevertheless, the preferences of the defendant physician typically exert a heavy influence on the insurer's decision to try or settle the case. Defense attorneys' recommendations to the insurer are often affected by the degree of rapport they enjoy with their physician client, the client's conviction (or lack of conviction) regarding whether he or she met the standard of care, and the level of the client's commitment to defending the case in a jury trial.

From the insurer's standpoint, the decision to settle a case is guided by a number of factors, such as (1) the strength and quality of the defense expert who has evaluated whether the standard of care has been met, (2) the reputation and ability of the plaintiff's trial counsel, (3) the likely verdict potential and the risk of an adverse verdict, (4) the general competence and demeanor of the defendant physician, and, of course, (5) the costs of mounting a defense, which include defense attorney fees, expert witness fees, expenses for daily transcripts during trial, technology costs associated with the preparation and trial of the case, and the likelihood of an extended and expensive appeal by the losing party after the verdict. Insurers also consider the potentially beneficial longer-range impact of earning a reputation for defending their clients against all

meritless claims, regardless of cost, on the assumption that strong and successful defenses against such claims will discourage future meritless claims against the physicians they insure.

From the standpoint of an insured physician who is a named defendant, the risk of an adverse verdict is, or should be, an important consideration, as should the emotional wear and tear incurred in preparing for and enduring the stresses of a trial; the time spent away from work and family; the degree to which a settlement, as opposed to a successful verdict, may affect future insurance premiums; and the extent to which a favorable jury verdict will result in clearing of the physician's good name and restoration of his or her professional reputation. How these considerations affect the decision between settlement and trial is strongly influenced by the psychological makeup of the defendant physician: a physician with a strong emotional support structure who also has a personality capable of standing up to the emotional stress and rigors of the courtroom is more suited to participation in a trial than a physician with a more fragile personality who is intolerant of criticism and distrustful of the jury and the legal system. A physician who favors going to trial over settling the claim should be willing to become fully invested in preparing the case for trial, should have a high degree of confidence in the preparation and skills of the defense attorney trying the case, and should be willing to spend the time required to read the voluminous pretrial discovery depositions, medical literature, and medical records associated with the case.

Many physicians would rather have professional negligence claims judged by other physicians than by laypersons from all walks of life and of different education levels. These attitudes have their roots in the 19th century, when the judicial system was struggling to resolve the claims of injured patients against a backdrop of inconsistent medical standards, relatively unsophisticated scientific knowledge and information technology, and antiquated means of communicating medical concepts to laypersons, many of whom were illiterate and lacked what would currently be considered a minimal education. Today, the situation is different: jurors with college degrees are the norm, rather than the exception, in many venues, and the expanded use of technology in the courtroom enables illustrations, concepts, and documentation to be displayed clearly and effectively while witnesses discuss and interpret them for the jury. Accordingly, it is likely that at least some of the traditional suspicion of lay juries may be misplaced. As Struve has noted, "Juries' liability determinations in malpractice cases are not random; rather, studies find some degree of correlation between jury outcomes and medical reviewers' findings of negligence and causation."¹¹ The statistics released for the year 2005 demonstrate that in Pennsylvania, more than 80% of the verdicts in malpractice trials courts continue to be rendered in favor of the defendant.¹²

It is noteworthy that medical malpractice cases seem to account for a far higher share of tort trials than other types of tort actions do. For example, in Philadelphia County in 1996, malpractice accounted for only 3% of tort case filings but 18.7% of tort trials. To make the comparison in another way, about one of every eight malpractice filings went to trial, compared with about one of every 100 automobile accident filings.¹³

Preparing for a Deposition

Depositions are part of the process of gathering evidence and information in preparation for a malpractice trial. They are often held in an attorney's office. State law controls depositions, so there is some variation, but, in general, they follow similar guidelines. During a deposition, you will usually be questioned by the plaintiff's attorney first, with follow-up questions asked by your own counsel during cross-examination. Additional questions by both attorneys are possible to further clarify points. The entire proceeding will be transcribed by a court reporter, and objections are allowed in most states. It is important to prepare for your deposition by reviewing the available records so that you are familiar with them. It is also important to take the time to understand the questions that you are being asked and to answer them carefully. Depositions may be used at trial to demonstrate inconsistencies in your answers to questions, so it is important to carefully consider answers before you give them. Your attorney can help you in your preparation for the deposition and is usually present while it is being taken.

How Should Surgeons Act When They Are Defendants or Witnesses in a Courtroom Trial?

Although the experience of a medical malpractice trial is not inevitable for all practicing physicians, it is a significant possibility for many. If the suit is held to have merit, no settlement has been arrived at and the case goes to trial, an understanding of what to expect at trial is helpful. In addition, strategies for more effectively, credibly, and persuasively presenting the defense of a medical case to a jury of laypersons charged with the duty to arrive at a verdict can be useful.

Many witnesses who have to testify in court feel frightened or intimidated as they approach the witness stand to be sworn in. Sometimes the truth that the witness is attempting to tell is distorted because of this fear and because of the tactics of the opposing lawyer. The perception and judgment of the jurors who listen to the witness are affected not only by what the witness says but also by the manner in which the testimony is given, the degree to which the witness is acclimated to the facts of the case, and the demeanor of the witness on and off the witness stand. Rightly or wrongly, how the witness testifies is often more critical than what he or she actually says. The jury members' responsibility is to weigh the facts that they are presented with and to come to a judgment. The trust that they have in the witnesses is a crucial element of this process.

Preparation for an appearance in the courtroom is critical for any physician testifying in a trial to best use the opportunity to present the facts in a fair and convincing light. Not surprisingly, under the stress of the moment, intelligent, experienced, and articulate witnesses often abandon their habits of good judgment and solid common sense the moment they walk into a courtroom. The guidelines presented are applicable to both physicians who are actual defendants in a medical malpractice trial and those who are merely witnesses.

GENERAL PREPARATION

Most persons who have rarely or never been a witness in a trial are nervous and anxious at the thought of testifying in

front of a jury. A major reason for this reaction is the fear that one's words will be twisted by the opposing lawyer or that the intended testimony will be unfairly distorted or misrepresented as a result of deceptively phrased trick questions. You can overcome, or at least alleviate, this nervousness and anxiety by preparing painstakingly and familiarizing yourself with the case well before the trial, as well as by concentrating on and paying close attention to the content of any questions posed by opposing counsel during your testimony.

Defense counsel should discuss the key case issues with you in detail before your appearance, but, obviously, not all questions and answers can be (or should be) rehearsed. For your part, you should make sure that you are thoroughly familiar with the portions of the medical records for which you are responsible (either directly or in a supervisory capacity). You should also read and study your pretrial deposition transcript to prevent inconsistencies in your trial testimony. If possible, you should review the pretrial depositions of other witnesses in the case. Stenographers are now able to generate word index transcripts that allow you to search the index of another witness's deposition, quickly find all locations in that deposition where the witness or the examiner mentions your name, and then focus on any portion of the testimony that has a bearing on you or your involvement in the case. Currently available trial presentation software also allows such searches to be linked to corresponding segments of the video portion of a videotaped deposition, with the written transcript appearing below the video as the witness testifies. This approach can be an extremely effective tool for a trial lawyer during cross-examination, in that it facilitates demonstration of inconsistencies in a witness's statements through verbal and visual comparison of trial testimony with a pretrial deposition.

Unless a sequestering order has been issued, you should try, if possible, to come to court to watch other witnesses testify before you. This will not only familiarize you with the process of cross-examination but will also help you feel more comfortable with the courtroom environment as a whole by the time you testify. Of course, if you are a named defendant in the case, you will have been there almost all the time during all phases of the trial anyway.

BEHAVIOR AT TRIAL

During Jury Selection

If you are a named defendant, it is very important that you be present during jury selection, a process known as *voir dire*, which is used in most states. At this time, you will first be introduced to the jurors who will be hearing the case. Some information is elicited from the potential jurors before the selection process actually takes place. You will have an opportunity to communicate with your counsel if you have any preferences or concerns about any individual potential juror. Each party to the case generally has a limited number of so-called peremptory challenges. This means that your counsel can eliminate a preset number of potential jurors for virtually any reason. In addition, each party has an unlimited number of so-called challenges for cause, which involve making the argument that a particular potential juror cannot sit on the case fairly and impartially. If the reasons underlying

this argument are demonstrated to the satisfaction of the judge during the questioning of the juror, the challenge is upheld; if not, it is denied.

Ideally, before the selection process begins, you and your counsel should spend some time discussing the qualities your team would like your jurors to have and developing a consensus on what responses to questions should be considered favorable and what responses should not. You should feel free to offer suggestions to your counsel regarding questions to ask the jurors, even if the questions you think of may seem obvious. In some instances, your counsel may retain jury consultants to assist in developing *voir dire* questions aimed at identifying positive or adverse jurors. In the last analysis, jurors are generally selected on the basis of nothing more than a hunch. Most of the time, decisions made during the selection process are based mainly on a "gut feeling" derived from observing the jurors as they react to the lawyer's questions during *voir dire*.

During Lawyers' Opening Statements

After the jury is empaneled, each side has the opportunity to make an opening statement to the jury before the evidence is actually presented. An effective opening statement can go a long way toward persuading the jury to accept one side's view of the case, even though the jury is cautioned by the judge to withhold judgment until all the evidence is heard. If you are not a named party to the case but merely a witness, you should still try to be present during the opening statements; doing so will help you quickly develop a feel for the case and will alert you to the issues you may face when you testify on the witness stand a few days later. In some instances, however, you may not have this option. Certain trial judges may allow opposing counsel to obtain a sequestering order preventing witnesses (but not parties) from being present during the opening statements or during the testimony of other witnesses.

During Presentation of Evidence

Because the burden of proof is on the plaintiff, the plaintiff's case commences first, after the opening statements. Sometimes the first witness called is not the plaintiff but the defendant (or one of the defendants if the suit was brought against multiple physicians). Plaintiffs' lawyers like to use this tactic early in the case, when the witnesses are likely to be more nervous and have not yet had time to observe and warm up to the pace and facts of the case. By applying this tactic, they hope to take advantage of the initial unfamiliarity with the testifying process, sometimes attempting to strong-arm a nervous or inexperienced witness or manipulate his or her testimony. Sometimes all the plaintiff's attorney is trying to accomplish is simply to make the witness appear unsettled, evasive, or defensive so as to prejudice the jury against that witness.

The upside of being called in the plaintiff's case as one of the first witnesses is that it gives you an excellent opportunity to present the defense's side before the plaintiff's points are firmly established in the jurors' minds. Although the questions asked in this situation are, of course, under the control of the plaintiff's lawyer, they may—depending on how narrowly they are phrased—yield you an opening through which you can make the central points of the defense at the outset of the case.

When being questioned by opposing counsel, you must pay close attention to how the questions posed to you are phrased and whether improper assumptions and inaccurate statements of fact are loaded into these questions before you answer. If the question contains an improper predicate or attempts to make you assume facts that are contested, you must point this out before you attempt to answer the question. At the same time, you must never be evasive or fail to give a truthful and direct answer if the questions are straightforward, fair, and simple.

After you have been questioned by the plaintiff's attorney to establish the basic facts the plaintiff needs to prove, your defense counsel may cross-examine you in an effort to make, through your testimony, as many key points for the defense as the judge will then allow, even to the extent of assisting the defense in introducing documents or exhibits that the jury has not seen before. The defense thereby has a chance to place its case before the jury before the plaintiffs rest their case. If all the key points for the defense can be established, it may not be necessary to call you back to the witness stand later, during the defense's formal presentation of its case after the plaintiff rests. The decision as to whether you will be recalled during the presentation of the defense is usually made later in the trial, well after the defense has formally opened its case. Defense counsel should prepare you for this possibility in advance of the trial so that you are aware of the critical defense points that should be made in your subsequent testimony.

Many defense attorneys elect to defer this type of pro-defense cross-examination to the formal presentation of the defense, the rationale being that it may be best to hold the strong points of the defense in reserve until after the plaintiff has taken his or her "best shots." You should discuss this issue with your attorney in advance of the trial and decide on the strategy that works best for you.

DEMEANOR AS A WITNESS

General Recommendations

Numerous trial lawyers, acting for plaintiffs and defendants alike, have observed that it is better to have a poor case with a client whom the jury likes than a good case with a client whom the jury dislikes. The particular challenge for the physician acting as a witness is to avoid the appearance of being disengaged, aloof, or, worse, arrogant. Therefore, when testifying on the witness stand, you should always convey an attitude of caring, concern, and respect for the patient who is the subject of the suit. As difficult as it may be, you should always be polite and respectful toward the opposing counsel who will be cross-examining you. If, as sometimes occurs, the opposing attorney treats you with disrespect or ridicule, you should not respond by becoming defensive or overly aggressive. If you act respectfully, the jury will invariably come to feel displeased with and offended by the attorney and will resent the attorney for continuing in this manner in the face of your professionalism and politeness. This is true even if the attorney otherwise appears to be making some powerful points during the questioning.

Above all, it is imperative to avoid the ever-present temptation to condescend to or ridicule the plaintiff's attorney during questioning on technical matters. Although it may

well appear to you that the opposing attorney is "out of his (or her) league" in trying to play doctor, your interests are not served by making this attitude apparent: the jury will quickly identify with and side with a lawyer who is patronized or belittled because of a lack of technical knowledge or mispronunciation of medical terms. If you are perceived as defensive, sarcastic, or hostile toward opposing counsel, the jury may well dismiss the logical point you are making on the witness stand out of a feeling of empathy for the examining attorney, especially if that attorney has been polite to you during the questioning. Physician witnesses, particularly those who are professors and researchers, must be on their guard not to be seen as arrogant, ivory tower types who are out of touch with the human, caring side of medicine (the side that jurors typically prefer to see). The jury generally wants to like you and understands that you are human. Building their trust is crucial.

You should refrain from humorous quips or anecdotes, especially if you are a defendant or a fact witness in the case. You should project your answers in a strong voice and look the examining attorney in the eye when questioned, but without appearing hostile in any way. If you do not know the answer to a question, the best response is simply to say so. You will get into difficulty if you continually try to outsmart the cross-examiner by trying to anticipate where the questioning is headed or giving equivocal or facetious answers.

When being examined by the plaintiff's attorney, you should try not to look at your own counsel at the defense table while the question is being asked, while you are answering it, or right after you have given your answer. Looking back at the defense lawyers with whom you have associated is a natural impulse, especially when the courtroom scene is strange to you and you feel a need for reassurance or approval. However, this impulse should be restrained because it suggests to the jury that you are unsure about your testimony or, even worse, that the testimony might never have been yours to begin with. You should look at the defense attorneys only when they are questioning you.

When medical concepts must be explained to a jury, it is important to avoid medical jargon. "Cause" is universally understood; "etiology" is not. Generally speaking, most medical concepts can be clearly explained with nonmedical words, basic illustrations, or even crude diagrams. However, the complexity level of your testimony and the extent to which you use technical medical language may vary depending on the point in the trial at which your testimony is given. For example, if you are the last witness testifying and the jury has already heard three physicians explain a particular medical issue, you risk insulting the jurors if you talk to them as if they are in a seventh grade health class; you are better served by using language that matches their current acquired understanding of the issue in question. You must use your own judgment as to what level of medical explanation is appropriate at any given point in the trial, but it is important that you are clearly understood.

Most jurors are keenly interested in medical science and human physiology. If you can respond to this interest by testifying in a clear and accurate manner, without condescension, you have a better chance of ensuring that the

technical aspects of your testimony are remembered and understood long after you leave the witness stand.

Strategy on Cross-examination at Trial

The strategy that should govern your testimony at the trial is quite different from the one that governed your testimony at the pretrial deposition. At the deposition, there was no jury, and your counsel instructed you to answer all questions concisely, without volunteering any information that would lead to more questions. At the trial, it may be to your advantage on occasion to play a more active role. For example, you may forcefully but politely correct a misimpression that is being conveyed by the cross-examiner's questions, or you may add another point that disputes a particular point the questioner is attempting to make. In doing so, however, you must maintain and convey a sense of balance and fairness because it is certainly not to your advantage to dispute or equivocate on obvious points.

Correction of Misleading Questions

If the cross-examining lawyer asks you a leading question that contains an unfair or improper assumption in the question itself, you should politely correct him or her and make it clear that you do not accept the assumption in the question.

Vulnerability to this sort of tactic is heightened when the examining attorney uses deposition testimony or characterizes a particular document during the formation of a question. It is astounding how often witnesses feel compelled to agree with the examiner's characterization of the testimony in a deposition or of the contents of a particular document, without even asking to see the portion of the deposition or document to which the examining attorney is referring in the question. Unless you know for certain that the portion of the deposition or document used in the question is characterized accurately, we suggest that you do the following:

1. *Always ask to see the deposition transcript or document referred to in the question before beginning to answer.* Quite often, the questioning attorney is taking the passage out of context, is ignoring relevant passages immediately before or after the passage quoted, or, even worse, is directly misrepresenting the content of the document or deposition passage in question. Most judges will accord a witness the courtesy of being provided with the document if the witness requests it. If, as sometimes happens, your request is not granted, this refusal may actually be to your advantage: jurors are almost certain to be sympathetic to any witness who requests to see a document and is denied the opportunity to see it.
2. *Do not answer the question until you have received the document you requested.* When you are given the document, ask for a moment to see the passage that was the subject of the question but take a few extra seconds to examine the paragraphs before and after the passage, both to confirm your understanding of the context and to determine whether the preceding and following passages help clarify the passage in question.
3. *If you then remember the question, answer it.* If you do not remember, ask the court reporter to read back the question after you have read the document. When you answer the question, correct any misrepresentation made in the question or add anything you have found that would

clearly establish that the passage was taken out of context or misquoted. If, however, the examiner's question was fair and accurate, simply concede that the passage says what was represented in the question and wait for the next question. Finally, if the judge denied your request to see the document before you answer, you are then permitted to testify that because you cannot recall the exact wording of the document referred to in the question, you are unable to answer the question.

Not surprisingly, witnesses who fail to follow these instructions often find their testimony to be unfairly mischaracterized and manipulated and sometimes discover that they have been tricked into conceding points that were untrue or unsubstantiated. A witness who does follow these instructions, however, will find, more often than not, that the examining attorney will abandon further attempts to misrepresent the document with him or her and will adopt a more measured and cautious approach to questioning.

It is important not to quibble about well-established facts or undisputed data that appear in medical records. A successful strategy is always to be on the side of facts that the jury will most likely regard as true—even if some of those facts, considered individually, do not appear to be favorable to the defense.

Handling of Cross-examination Questions Based on Deposition Transcript

Questions referring to your own pretrial deposition transcript should be dealt with in precisely the same manner as questions based on any other documents (see above). You should ask to see the transcript, you should review its context before beginning your answer, and when you answer, you should take the chance to correct any misleading assumptions or add crucial context. It is to your advantage that your cross-examination testimony be consistent with your deposition insofar as this is possible. Unprepared trial attorneys sometimes make the mistake of trying to impeach a witness with a document that, instead of contradicting the witness's testimony, turns out to be consistent with it, thereby strengthening the very point under attack. This tactic can cause the lawyer to lose all credibility in front of a jury, especially when the witness can politely explain why the previous testimony is consistent with the current testimony.

Another unfortunate tactic some lawyers use with deposition transcripts is to suggest that the witness just testified inconsistently because the in-court testimony did not appear in the deposition at all. For example, the examining lawyer might say to the witness, "You just testified here in court that 'fact A' occurred. Show me where in your deposition you ever testified that 'fact A' occurred." The witness should then say something like the following: "At the deposition, I was instructed to answer only the questions asked. I looked at my deposition before testifying today, and I do not believe that you ever asked me about 'fact A' in my deposition. If I am mistaken, could you show me the point in my deposition where you asked about that subject?"

Handling of Exhibits

When you are handed any exhibit, whether it is a demonstrative exhibit or some other record in the case, you should make a point of holding it and moving it with care and

respect. This nonverbal communication with the jury is important because it is representative of your caring and respectful attitude toward the entire case. If you are asked to identify an exhibit, you should take the time to examine it carefully before verbally identifying it.

When you are asked to show the exhibit to the jury or to explain something while using the exhibit, you should first ask for permission to step down from the witness box and then place the exhibit on an easel or otherwise position it and yourself in such a way that you do not obstruct any juror's view of the exhibit as you are testifying. During your testimony, you have an excellent opportunity to make eye contact with each juror and build a rapport. Sometimes, in dealing with an exhibit, you will have to face away from the court reporter. Therefore, you should make sure that you always speak loudly enough to be heard easily by the court reporter so that the key portions of your testimony will not be interrupted by the court reporter's requests for you to repeat a statement or to speak louder.

Conduct While Not Testifying

When your testimony is concluded, or when the judge orders a pause, you should not attempt to communicate non-verbally with any of the attorneys, parties, or other witnesses. You should walk away from the witness chair with an erect and confident posture and resume the seat you occupied before you testified (unless you have been dismissed from the courtroom by the judge).

While other witnesses are testifying in the courtroom, you must avoid any emotional facial expressions signaling either approval or disapproval of the witnesses or the attorneys. Facial expressions showing exasperation, disbelief, approval,

or other emotions will be seen by the jury as contrived and self-serving and may cause you to be perceived as less objective, factual, and trustworthy. You should also endeavor to distance yourself physically from other defense witnesses who are in the room to avoid the appearance of collusion. If you are a defendant or the physician whose care is being called into question, you should not wave to or acknowledge any other witnesses (including the defense expert) who may come into the courtroom during the proceedings when the jury is in the room.

You should not stare or smile at the jurors: they will resent any attempt, subtle or overt, to influence or curry favor with them. Especially if you are sitting at the counsel table, it is a good idea to take notes occasionally during the proceedings or to have something in front of you at the table to read. If you have a suggestion to make to your attorney during another witness's testimony, you should write it down and hand the note to the attorney or else discuss the matter during the next recess.

During recesses, at lunch, in the elevator, or en route to or from the courtroom, you must be extremely careful not to discuss the case with anyone if there is a risk that you may be overheard by a juror or a friend of the plaintiff. During recess, when the jury is not in the courtroom, you may want to converse with courtroom personnel, witnesses, attorneys, or other persons in the courtroom. Once the bailiff has called for the jurors, however, you should return to your seat promptly, before the jurors return to the courtroom. Again, you should be careful not to stare at the jurors as they leave and enter.

Financial Disclosures: None Reported

10 SURGICAL PALLIATIVE CARE: CLINICAL AND ETHICAL CONSIDERATIONS

Anne C. Mosenthal, MD, FACS, and Geoffrey Dunn, MD, FACS

The last 15 years have seen a renewed interest in and concern about the end of life and the care of the dying, both in American society and in the practice of medicine and surgery. This can be traced to the growth of the hospice movement, patient-centered care, and the change in demographics permitting many more adults to live longer with chronic, life-limiting illness. Simultaneously, it can also be seen as a reaction to the increasing emphasis of American medicine on technology, cure and prolongation of life at the expense of the relief of suffering, humanism, and the “art” of medicine. The last decades of the 20th century saw an unprecedented growth in life-prolonging technology but also an increasing awareness of the erosion of the doctor-patient relationship, the dehumanizing effect of much of medical care, and the shift from physician as healer to physician as technician and gatekeeper. The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) in the 1990s observed that most Americans died in institutions, usually on life support, with untreated pain and suffering,^{1,2} yet most Americans wish to die at home and fear untreated pain and artificial extension of life.³ At the same time, ethical and judicial decisions that emphasize patient autonomy provided the legal foundation for the care of the dying today, ensuring that physicians can both relieve suffering and avoid burdensome or futile treatments for their patients at the end of life. The convergence of these developments has perhaps fostered the renewal of the twin goals of medicine and surgery: the relief of suffering alongside life-prolonging, curative therapy.

Surgical palliative care has evolved in this context over the last 10 years, drawing not only from the fields of hospice and palliative medicine but also surgery itself. The emergence of this field of surgery has in one sense reclaimed the long surgical traditions of palliation and compassion from a time when to bear witness and relieve suffering were all the surgeon could offer, attributable in part to the limitations of medical knowledge or surgical technique. Historically, much of surgery and surgical care has focused not on cure but on palliation of symptoms and restoration of quality of life, with burn care, vascular surgery, and surgical oncology being prime examples. The contemporary practice of surgery now includes the integration of technical competence with knowledge and skill in relief of suffering, restoration of quality-of-life, communication, and, when the end of life is near, appropriate decision making and withholding or withdrawing of life support. The following chapter describes the evolution of surgical palliative care, its ethical basis, and its approach and clinical applications in surgical practice.

Evolution of Surgical Palliative Care

The roots of surgical palliative care can be traced first to the hospice movement founded by Dr. Cicely Saunders in the 1960s. She focused on the needs of the terminally ill, particularly their intense suffering from untreated pain at the end of life. She defined the model of “Total Pain” and distinguished “pain” from “suffering.” She described the four dimensions of pain as physical, psychological, social/economic, and spiritual, which lead to suffering. Hospice care developed to treat all four aspects of pain, for both patient and family, at the end of life. This model focused initially on those dying of cancer, where the trajectory of illness encouraged the aggressive treatment of suffering only when death was imminent or life-prolonging care had been exhausted.

During the 1980s and 1990s, palliative care extended this model of care to patients dying of other illnesses, such as dementia, cardiovascular disease, and organ failure, where the trajectory of decline is long and unpredictable and the dichotomy of cure versus comfort is blurred. Concomitantly, other concepts of suffering, such as that proposed by Eric Cassell, brought the realization that medical care itself might be the cause of suffering rather than the relief. He described suffering as arising from a threat to the integrity or wholeness of a person. Cassell noted that “the relief of suffering and the cure of disease must be seen as twin obligations of a medical profession that is truly dedicated to the care of the sick. Physicians’ failure to understand the nature of suffering can result in medical intervention that (though technically adequate) not only fails to relieve suffering but becomes a source of suffering itself.”⁴ Now palliative care has evolved to a model of interdisciplinary care that aims to relieve suffering and improve quality of life for patients with advanced illness and their families. It is offered simultaneously with all other appropriate medical treatment.

In 2010, surgical palliative care has evolved from these trends in palliative care and long traditions in surgical care. Although the goal of cure is paramount in much of surgical care, the relief of suffering and palliation of symptoms are equally important. The core values of surgical culture include ethical decision making, preservation of hope, nonabandonment, relief of suffering, and improvement in quality of life. Certainly, surgeons have always prided themselves as being the doctors of last resort, taking on the most difficult cases and thereby maintaining hope and presence when others have “given up.” Coronary artery bypass graft for the treatment of angina, organ transplantation, and vascular surgery were developed as palliative procedures, with their primary goal to

improve quality of life as well as prolong it. Fields such as burn care, trauma, and critical care are examples of surgical specialties that emphasize not only aggressive, technology-based, lifesaving care but also aggressive attention to pain relief, rehabilitation, and quality of life. Both are considered equally important, neither is mutually exclusive, and usually both are delivered simultaneously to patients.^{5,6} It is no surprise, therefore, that surgical palliative care would be embraced as a specialty inasmuch as it is a renewal of core surgical values and the adoption of other disciplines.

Contemporary practice of end-of-life care was officially recognized in the surgical profession when the American College of Surgeons endorsed its *Statement of Principles Guiding Care at the End of Life* in 1998 [see Table 1].⁷ Over the next decade, the principles of end-of-life care were integrated into the surgical canon, and the palliative approach to care was moved upstream to include those patients with chronic, serious illness and the critically ill, not just those who are imminently dying. In 2005, the American College of Surgeons endorsed the *Statement of Principles of Palliative Care* [see Table 2],⁸ thereby codifying a new discipline of surgery. Over the last 10 years, the field of surgical palliative care has grown, culminating in recognition by the American Board of Surgery and the American Board of Medical Specialties as a distinct discipline with board certification.

Ethical and Legal Foundations of Palliative Care

The current practice of palliative and end-of-life care is guided by bioethical principles and established judicial decisions. The vast majority of deaths in America now occur in hospitals and institutions, where active decisions must be made to withhold or withdraw interventions to allow a “natural” death. Over 70% of patients dying in an intensive care unit have at least one intervention withheld or withdrawn prior to death.⁹ Surgeons must be familiar with the ethical principles and judicial decisions that form the basis of this practice.

Clinical decisions in palliative care are grounded in the four ethical principles that guide all of modern medicine: autonomy, beneficence, nonmaleficence, and justice [see

Table 1 American College of Surgeons Statement of Principles Guiding Care at the End of Life

Respect the dignity of both patient and caregivers.
Be sensitive to and respectful of the patient's and family's wishes.
Use the most appropriate measures that are consistent with the choices of the patient or the patient's legal surrogate.
Ensure alleviation of pain and management of other physical symptoms.
Recognize, assess, and address psychological, social, and spiritual problems.
Ensure appropriate continuity of care by the patient's primary and/or specialist physician.
Provide access to therapies that may realistically be expected to improve the patient's quality of life.
Provide access to appropriate palliative care and hospice care.
Respect the patient's right to refuse treatment.
Recognize the physician's responsibility to forego treatments that are futile.

Adapted from the American College of Surgeons.⁷

Table 2 Statement of Principles of Palliative Care

1. Respect the dignity and autonomy of patients, patients' surrogates, and caregivers.
2. Honor the right of the competent patient or surrogate to choose among treatments, including those that may or may not prolong life.
3. Communicate effectively and empathically with patients, their families, and caregivers.
4. Identify the primary goals of care from the patient's perspective and address how the surgeon's care can achieve the patient's objectives.
5. Strive to alleviate pain and other burdensome physical and nonphysical symptoms.
6. Recognize, assess, discuss, and offer access to services for psychological, social, and spiritual issues.
7. Provide access to therapeutic support, encompassing the spectrum from life-prolonging treatments through hospice care, when they can realistically be expected to improve the quality of life as perceived by the patient.
8. Recognize the physician's responsibility to discourage treatments that are unlikely to achieve the patient's goals and encourage patients and families to consider hospice care when the prognosis for survival is likely to be less than a half-year.
9. Arrange for continuity of care by the patient's primary and/or specialist physician, alleviating the sense of abandonment patients may feel when “curative” therapies are no longer useful.
10. Maintain a collegial and supportive attitude toward others entrusted with care of the patient.

Adapted from American College of Surgeons.⁸

Table 3].¹⁰ Each clinical situation requires consideration of all four principles for each patient; however, frequently, fulfillment of one principle conflicts with fulfillment of others. For example, a surgeon may perform a surgical procedure that can successfully remove a cancer (beneficence) but may cause pain or even death from complications (nonmaleficence). Treatment of pain may be beneficial but can theoretically hasten death in some cases. Patients may refuse lifesaving surgery (autonomy) even if it means imminent death or disability. The ethical principle of double effect allows the surgeon to perform surgery and aggressively treat pain and suffering at the end of life if the *intent* is to do good, even though the side effect of the treatment may harm the patient. The bad effect may be a foreseen, but not intended, consequence or purpose of the treatment.

In Western culture in general, and the United States in particular, the principle of autonomy has been codified and supported by the judicial and legal system as the prevailing ethical principle to guide medical decision making. Patient autonomy is considered a fundamental right of Americans; this includes the right to be informed about medical illness, prognosis, and treatment options and the right to choose or refuse these options even if they are lifesaving. The Patient Self-Determination Act of 1990, passed by the US Congress, legally ensures that patients have the right to facilitate their own health care decisions, accept or refuse medical treatment, and create an advance directive. This allows patients to determine their future health care decisions by completing a living will. Surgeons are ethically and legally bound to observe the wishes set forth in a living will in the event the patient becomes incapable of making such decisions. In practice, however, this is complicated by the reality that specific clinical scenarios are rarely laid out in a living will, situations

Table 3 Common Ethical Issues in the Practice of Surgical Palliative Care

Issue	Commentary
Disclosure of bad news	Broad legal and ethical consensus supports disclosure of bad news when permitted by patient or surrogate. Disclosure of bad news does not “take away hope” if conveyed with empathy in the spirit of nonabandonment. Empathic truth telling fosters trust, which is the basis of hope.
Perioperative do-not-resuscitate (DNR) orders	The American College of Surgeons, the Association of Operating Room Nurses, and the American Society of Anesthesiologists support a policy of “required reconsideration” of DNR orders in the perioperative period. This is a preoperative discussion between patient/surrogate and anesthesiologist and surgeon to clarify goals and limits of care, with either revision or continuation of the DNR order in the operating and recovery room. Automatic rescinding of DNR orders during surgery is not recommended.
Withholding/withdrawal of life support	The withholding of medical treatments is considered legally and ethically equivalent to withdrawal. This is based on the principle of autonomy. In practice, for both physicians and surrogates, it is more difficult to withdraw a life-supporting treatment once it has been started than to withhold it. A surrogate’s persistent reluctance to consider termination of life support is usually related to the fear that he or she will be “killing the patient” or the fear that withdrawing life support will cause suffering. Legally and ethically, termination of undesired medical treatment of the properly informed patient/surrogate is not considered homicide, suicide, or euthanasia.
Aggressive symptom management	Aggressive management of unbearable symptoms at the end of life is a moral imperative, even at the risk of hastening or causing death, as long as causing death is not the intention of treatment. The risk of hastening death is present with any surgical treatment for serious illness, including attempts to cure. The rule of double effect, broadly accepted by ethicists, is invoked: • The act must be good or morally neutral. • Bad effects are foreseen but not intended. • A good end cannot justify a bad means. • The risk/benefit ratio must be reasonable.
Donation after cardiac death (DCD)	Ethical and legal principles support DCD, invoking principles of autonomy and double effect. DCD should be considered for patients where withdrawal of life support is contemplated. The Organ Procurement Organization personnel should be consulted prior to decision making to evaluate feasibility and medical suitability before approaching this option.

arise that are unforeseen, and written documents cannot substitute for informed discussions between physician and patient. This reality has led to reliance on surrogate decision makers and health care proxies to interpret a patient’s living will or advance directive in consultation with the physician. Although the Patient Self-Determination Act did not specifically address the issue of surrogate decision maker or the ethical basis of substituted judgment in medical decision making, the legal and ethical basis has been clearly established by the Supreme Court decisions of the Karen Anne Quinlan and Nancy Cruzan cases.^{11–13} These two cases established that it is consistent with autonomy, beneficence, non-maleficence, and justice if a surrogate decision maker acts based on the patient’s best interest and/or in accordance with the patient’s previously expressed wishes. This provides the legal basis for decisions to withhold or withdraw life support in patients who are incapacitated, as long as these principles are maintained.

The Practice of Surgical Palliative Care

Surgical palliative care is the treatment of suffering and the restoration of quality of life for seriously ill or terminally ill patients with surgical disease, regardless of the prognosis. The surgeon brings all the tools in his or her armamentarium to treat distress, not just disease. The measure of surgical palliative skill in this context is not disease specific, such as complications, morbidity, or mortality, but rather patient

centered. Quality of life, relief of symptoms, and the opportunity for spiritual comfort or closure at the end of life are more important measures of success in this discipline. This constitutes a cultural shift in surgery, where the morbidity and mortality conference reinforces the notion that death is a “failure” of the surgeon and brings “shame” on him or her.¹⁴ It is not a large leap to see how this stigma would cause some surgeons to view end-of-life care as the sine qua non of “giving up” and therefore distinct from their aggressive, life-prolonging care. Surgical palliative care is currently moving away from this false dichotomy to an affirmative concept upstream in the patient’s care, when symptom control and restoration of quality of life can be delivered alongside life-prolonging surgery.

PALLIATIVE CARE ASSESSMENT

The first goal of the assessment for palliative care is to gauge the level of overall distress. The assessment is, in a sense, a “staging procedure” to determine the scope and severity of palliative care needs. Palliative care assessment includes the identification of the current illness, treatments, and likely prognosis; sources of pain in all dimensions; personal, social, and spiritual resources; and individual values and hopes. The patient’s decision-making capacity, advance directives, and health care proxy should be identified as well. Table 4, adapted from the American Medical Association Education for Physicians on End-of-Life Care Curriculum (EPEC), describes the domains of palliative care assessment

Table 4 Ethical Principles in Palliative Care

Principle	Ethical Imperative
Autonomy	Respect the capacity of individuals to make their own choices and act accordingly
Beneficence	Relieve pain and suffering, foster the interests and well-being of other persons and society
Nonmaleficence	Do no harm; do not inflict pain or suffering
Justice	Act fairly; distribute benefits and harms equitably

Adapted from Beauchamp TL and Childress JF.¹⁰

with sample questions for each. Immediate relief of pressing symptoms should be a priority and initiated concurrently with the assessment if necessary. Further discussions around goals of care cannot ensue if untreated symptoms are allowed to persist. Who should be included in the discussions should also be established at this time as the patient may or may not want family present.

The assessment of physical symptoms is usually the first priority in palliative care. This is focused on pain and non-pain symptoms, that is, the patient's subjective report, not on disease processes or disease-based review of systems (Table 5). The patient's self-report is the gold standard. Validated pain assessment tools using numeric scoring from 0 to 10 are the most common. Assessment tools are also available for nonpain symptoms but are generally validated for specific disease or patient populations. The Edmonton Symptom Assessment Scale (ESAS) is a validated tool for palliative care patients and includes assessment for nonpain symptoms such as fatigue, thirst, dyspnea, and nausea.^{15,16} Assessment should include not only the severity of the symptom but also questions as to the level of distress the symptom causes.

GOALS OF CARE

The patient's goals of care that emerge from this initial assessment and discussion should guide the scope of all further surgery and treatments. The goals of care are generated by the patient's preferences and wishes in the context of the medical realities and the prognosis. Goals may be fluid and evolve over time. Singer and colleagues identified five domains of quality of life that patients with life-limiting illness hope for: adequate pain and symptom management, avoidance of inappropriate prolongation of dying, sense of control, relief of burdens, and strengthening of relationships with loved ones.³ More recent studies suggested that seriously ill patients weigh treatment options based on the treatment burden, treatment outcome, and likelihood of the outcome, with cognitive or severe functional impairment often considered more unacceptable outcomes than death.¹⁷ Although the surgeon must elicit preferences from the patient, he or she must provide the medical information and prognosis to the patient, especially likely and unlikely outcomes from contemplated therapy. Physicians are notoriously poor at prognostication, but ranges of life expectancy can be provided, keeping in mind that in some disease trajectories, death may be years away, but chronic, debilitating decline may be the life-limiting feature. Some trajectories are more predictable, such as cancer, and assessment of function, or progression of symptoms, is an indication of life expectancy. The Karnofsky Performance

Scale score is a widely used scale for the assessment of function and prognosis in cancer patients.¹⁸ Patients with congestive heart failure or chronic respiratory failure who may be contemplating surgery have a more unpredictable trajectory to death but will need prognostic information about the likely decline in quality of life over time, with or without surgery.

All therapy should be evaluated by both patient and surgeon based on the goals of care established. Surgery or procedures are weighed, not by their defined complications or indications but by their benefits or burdens for the patient, in the context of his or her goals. Palliative surgery to relieve malignant bowel obstruction should be considered based on the likelihood of eating again and the relief of nausea, vomiting, and pain (benefit) versus the likelihood of pain, open wounds, infection, or death in the operating room or the hospital (burdens). The patient's decision will depend on his or her goals ("I want to die at home," "I want to see my daughter's wedding"), as well as the information the surgeon provides about the surgery and alternatives. Each treatment or therapy should be considered independent of other therapies and based solely on its benefits or burdens. Patients who want do-not-resuscitate (DNR) orders in the event of cardiopulmonary arrest will still need symptom relief or simple, life-extending treatments. Surgery to relieve malignant obstruction or antibiotics to treat pneumonia would still meet their goals, even if they do not want cardiopulmonary resuscitation (CPR).

Establishing goals of care can be a difficult transition for both patient and surgeon. The surgeon is often consulted as the last hope and held up as the "rescuer," bringing lifesaving surgery or other "miracles." It is not difficult to see that changing the goals of care is, in a sense, breaking this "covenant for cure"; the surgeon may feel that he or she is "taking away hope" or abandoning the patient by not performing futile surgery that would only add burden, not benefit.^{14,19} Conversely, the surgeon may have a long relationship with a patient, always focusing on aggressive, life-prolonging care, but now the prognosis has shifted, and a transition to comfort and relief of suffering changes this role. This is further complicated if the patient's condition has changed after surgery because of complications or iatrogenic events; this is frequently the case in the intensive care unit when unforeseen postoperative events have changed the course or patients linger with multiple organ failure and uncertain prognosis. The ability of the surgeon to reflect on his or her own sense of failure or loss is the first step in making a transition in goals of care. The surgeon has the unique role of helping the patient and family find new hope, whether it is hope for symptom relief or time with family. If likely outcomes are uncertain, the surgeon can convey this range of possibilities, and goals of care can include a focus on relief of suffering alongside other life-prolonging therapies, not in an either/or fashion.

INTERDISCIPLINARY TEAM

The relief of "total pain" or suffering requires an interdisciplinary approach, particularly if suffering is extreme. The collaboration of pain medicine specialists, clinical pharmacists, palliative medicine and nursing colleagues, and spiritual and psychosocial care providers is essential. Surgeons may not be familiar with nonsurgical alternatives for treatment of nonpain symptoms. Similarly, the best approach to breaking

Table 5 Palliative Care Assessment

Domain	Sample Questions to Ask the Patient
Illness/treatment summary	Tell me what you know about your illness. Could you give me an account about your illness and treatment you have had until now? Tell me what stands out in your memory (about your illness, about treatment to date). I will review (have reviewed) your medical history in your chart, but I am really interested in hearing about it from your point of view.
Physical symptoms	How long have you had (symptom)? Are you having this (symptom) all the time or on and off? How would you describe what you are feeling? Is the (symptom) staying the same, getting better, or getting worse? Using a scale (provide a scale), what is the lowest you have been in the past day? The highest? Where are you now? Does anything make the (symptom) better? Worse? To what extent does the (symptom) interfere with what you want to do? Is the (symptom) causing problems in your relations to others? Have any treatments helped your (symptom)? How much? What do you think is causing it (symptom)? Does it (symptom) frighten you? Why?
Psychological symptoms	Does everything happening make any sense to you? What do you think will happen next? How has your illness affected your life? What do you see as the biggest problem facing you now? What frightens you most about your illness? How would you describe your mood? How well do you think you are coping now? Do you feel depressed? Have you ever thought of taking your life? Do you have a plan? Have you been sad? Frightened? Anxious? Are you afraid of being a burden to others? How have you handled tough times in your life previously? Whom do you turn to for support in tough times? Have you ever had problems with depression, alcohol, or other psychological difficulties before your illness? Did you ever have treatment for these? Are you afraid we won't be there when you need us?
Spiritual issues	Do you consider yourself a religious or spiritual person? How important is your faith or belief in your life? Do you belong to a community of faith? What sustains your hope? Do you have religious or spiritual beliefs that help you through difficulty? What gives your life meaning? Does your faith influence your feelings about your illness? Your surgery? Do you see any possible conflicts between your health care and your beliefs? Do you have any specific observances or rituals we should be mindful of during your care?
Social/cultural context	Can you tell me about other people in your everyday life, at work, at home, etc.? What language is spoken in your home or community? Do you have a community or spiritual leader whom you would like to involve in your medical decisions?
Communication preferences	Is it your preference to be alone or have someone close to you present when we discuss important matters? Is there anyone with whom you would like me to discuss your care? If I am approached by family members with questions about your situation, do I have your permission to discuss it? To what extent?
Decision making	Who will make decisions about your medical care if (when) you are not able to? What would you like them to know?
Practical concerns	Where do you hope to go after this hospitalization? When you are ready for home, will your home be ready for you? Are you concerned about being a financial burden on your family?
Anticipatory planning	Have you given any thought of what comes after your hospitalization? What plans have you made for your future? Are there things you need to know right now for planning for the future? Would it be helpful for us to schedule a meeting with us and your family to plan your future treatment and care?

Adapted from palliative care assessment in EPEC, American Medical Association's Education for Physicians on End-of-life Care. 1999.

bad news, communication under conflict, or relief of existential pain may be beyond the scope of the usual surgical practice. In palliative care, the patient and family are considered part of the unit of care. Attention to bereavement, grief, and the needs of family at the end of life is especially important. Studies show that the nature of communication, access to the dying patient, and the patient's relief of distressing symptoms all affect the bereavement outcome of family members.^{20,21} Furthermore, the majority of hospitalized patients, particularly in the intensive care unit, are incapacitated and cannot make any medical or end-of-life decisions for themselves. Decision making generally falls on their surrogates, who are likely in crisis themselves because of the illness of a loved one. Emotional and educational support for their decision-making role is critical in avoiding conflict or prolonging the dying process, whether in the form of bereavement counselors, pastoral care, or other members of the palliative care team. Studies clearly show that interdisciplinary communication, whether in the form of family meetings, ethics, or palliative care consultation, has a salutary effect on both patient and family psychosocial outcomes.²²⁻²⁴ Surgeons may also benefit from this team approach as they seek balance in the dual imperatives to rescue and to relieve suffering. The death of a patient is also a loss for the surgeon; reflection and the ability to seek support are important steps for adapting to the multiple roles of the surgeon in palliative care.

COMMUNICATION

Shared decision making between the physician and the patient/family is the foundation of end-of-life care. Communication of bad news, along with treatment of distressing symptoms, is perhaps the fundamental "procedure" of palliative care. The emphasis on patient autonomy, the patient-doctor relationship, and professionalism and the realization that clinical and litigation outcomes are improved now require competency in communication skills in all aspects of surgical practice. Although as late as the 1960s, most physicians did not reveal a distressing diagnosis to their patients, it is now the expectation and legal obligation that all medical information be disclosed, no matter how upsetting. Communication around death and dying can be one of the most stressful aspects of practice. Surgical myths and fears abound: surgeons are poor communicators or lack empathy, truth telling will take away hope, talking is too time consuming—all further compound these stressful encounters. In fact, good communication is a skill. Increasing studies demonstrate that patients and families' satisfaction and understanding of the illness are improved when physicians do less talking and more listening, impart information clearly and simply, allow time and space for emotion, connect the emotional distress with its source (the medical information), and provide support.²⁵⁻²⁷ Several communication protocols for delivering bad news or conducting a family meeting have been proposed and studied.^{28,29} The SPIKES protocol developed by Baile and colleagues is one example, as shown in Table 6.²⁹ All of these emphasize preparation for the meeting, the appropriate setting, providing a "warning shot" for bad news, clear delivery of information, empathic reflection of emotion, and concluding with recommendations for treatment. Following these steps will provide support to the patient and family and allow for further communication. This is particularly

Table 6 SPIKES: A Six-Step Protocol for Delivering Bad News

Step 1: S – Setting Up the Interview - Arrange for some privacy - Involve significant others - Sit down - Make connection with the patient - Manage time constraints and interruptions
Step 2: P – Assessing the Patient's Perception
Step 3: I – Obtaining the Patient's Invitation
Step 4: K – Giving Knowledge and Information to the Patient - Avoid medical jargon - Give information in small amounts at a time
Step 5: E – Addressing the Patient's Emotions with Empathetic Responses - Allow time for expression of emotion - Identify patient's emotion - Identify cause of emotion - Connect emotion with cause of emotion
Step 6: S – Strategy and Summary - Discuss goals of care - Treatment plans - Future meetings

Adapted from Baile WF et al.²⁹

important when end-of-life decisions will be discussed; if initial communications are not clear and compassionate, conflicts around withdrawal and withholding of life support can ensue. The timing of communication is important, particularly with families of critically ill or injured patients. Family meetings to discuss prognosis and end-of-life decisions in the intensive care unit are more effective if held within 72 hours of admission.^{22,30}

WITHDRAWING AND WITHHOLDING OF LIFE SUPPORT

The vast majority of deaths in the United States, whether in the hospital or at home, now occur in the setting of withdrawing or withholding of life support. Although use of hospice during the last months of life has increased in the last decade, multiple studies suggest that the largest percentage of Centers for Medicare and Medicaid Services expenditures result from high-technology care in hospitals and intensive care units in the last 6 months of life.³¹ Death after end-of-life decision making and withholding or withdrawing of life support have become the norm, and expertise in this area is now part of standard surgical practice.

The process of withholding or withdrawing life support is based on shared decision making around end-of-life issues between patient, family, physician, and other health care providers. The decision should be based on patient preferences and goals, knowledge of the likely outcome of continuing life support versus withdrawing it, and the benefits and burdens of each option. Conducting these discussions requires skill in communication and knowledge of the ethical issues, symptoms, and therapies available to treat them. There continues to be misunderstanding around the difference between withdrawal of life support, euthanasia, and physician-assisted suicide. Families may worry that if they decide to withdraw the ventilator they "are killing the patient"; similarly, they

fear that their loved one may “suffocate.” Part of the discussion should include assurances that dyspnea, pain, and other symptoms can be treated successfully and that physicians will not abandon the patient once a decision is made. The “DNR discussion” can be particularly difficult; following available guidelines is helpful.³² These include the basic steps of good communication: preparation, appropriate setting, and reflecting troubling emotions around difficult issues. It is helpful to describe CPR as a procedure with certain indications, benefits, and burdens and to make a recommendation about whether or not to withhold it based on the medical prognosis and condition.

Confusion on the part of physicians still exists about their role in withholding and withdrawing life support. Many are more comfortable withholding therapy rather than withdrawing it because of unfounded fears that they may be causing death, abandoning the patient, or vulnerable to litigation. Historically, several studies have noted high variability in physician practice around DNR orders, withdrawal, and withholding, with some preferring to withhold rather than withdraw, whereas others withdraw therapy in a particular sequence or avoid withdrawal of the ventilator altogether.^{33–36} Ethical and legal precedents are clear that withdrawing is equivalent to withholding and the decision for each therapy should be based on patient’s preference (autonomy) and burdens and benefits.³⁷

Withdrawal of the ventilator deserves special consideration as it is a procedure that continues to cause anxiety among physicians. Several protocols have been developed for this procedure, which include family and patient preparation, use of terminal wean versus direct extubation, and guidelines for the use of opioids and benzodiazepines for the treatment of refractory dyspnea.³⁸ It is ethically and legally sound to

aggressively treat dyspnea with opioids based on the principle of double effect. The fears of hastening death by administration of opioids or benzodiazepines have not been borne out in several studies, where the time to death was equivalent for patients who did and did not receive these medications after withdrawal of the ventilator.^{39,40}

The practice of withdrawing life support can be perceived as a conflict between the patient-centered goals of palliative care and societal goals of organ donation. In fact, the two are not mutually exclusive. If the patient is likely to proceed to brain death and organ donation is possible, efforts to stabilize and support a patient can coincide with attention to patient’s pain relief and comfort and family support until brain death protocols are completed. In other clinical situations near the end of life, once the surgeon contemplates withdrawing or withholding life support for a patient, the issue of organ donation must also be considered. With the advent of donation after cardiac death (DCD), it is theoretically possible for patients to donate organs if cardiac death ensues after withdrawal of the ventilator or pressors. For some families, the prospect of organ donation is comforting in the face of otherwise bad news. Organ Procurement Organization personnel should be contacted prior to any communication with the family about this option to evaluate if medically appropriate. Any request for organ donation should be made by the organ procurement organization, not the physician caring for the patient. The decision to withdraw life support should be made before and separately from any consideration of organ donation. With DCD, organ donation may increasingly become part of the end-of-life decisions around withdrawal of life support.

Financial Disclosures: None Reported

11 BEDSIDE PROCEDURES FOR GENERAL SURGEONS

M. Margaret Knudson, MD, FACS, and Ramin Jamshidi, MD

Innovative equipment and advances in pain management have helped to expand the number and types of procedures that can now be performed safely and comfortably at the bedside of the surgical patient. However, success is unlikely unless the surgeon has detailed knowledge of the procedure, has assembled in advance all of the necessary equipment, and has a thorough appreciation for potential complications. Equally important is preparation of the patient for what he or she will experience and involvement of the responsible nurse prior to initiating any procedure. This chapter focuses on these essential aspects for each technique described. Additionally, we offer suggestions about training for and attaining competencies in these areas for surgeons in various stages of their professional careers.

Ultrasound-Guided Procedures

GENERAL PRINCIPLES: INSTRUMENTATION AND SCANNING TECHNIQUES

Over the past several years, ultrasonography has emerged as an increasingly useful bedside imaging technique, offering sharp two-dimensional and even three-dimensional imaging capabilities housed in smaller and more portable units. Thus, a working knowledge of ultrasonography is essential for a general surgeon and is now a requirement for all certified surgical training programs. Although a wide variety of excellent ultrasound machines are available from several manufacturers, the basic instrumentation and scanning techniques that are common to all are reviewed here.

In general, obtaining an ultrasound image begins with providing a path for transmission of the sound wave between the transducer and the object being scanned. This process, which is termed coupling, is accomplished at the bedside by replacing the air between the transducer and the skin with a gel surface (contact coupling). Standard ultrasound gels can be heated to enhance imaging and improve patient comfort, but, most importantly, these gels should be applied liberally to the skin for optimal imaging. In fact, if the object of interest appears dark on the screen, it is likely that the amount of contact gel is inadequate. The second major focus for the surgeon sonographer is choosing the correct transducer. The frequency of the transducer (measured in megahertz) determines the depth of penetration in the tissues; a low-frequency transducer travels deep in the tissue but loses resolution. For sharper images on the surface, one would choose a high-frequency transducer, which penetrates only a few centimeters deep. Table 1 describes the uses for transducers of various frequencies.

The image seen on the screen while scanning in real time is produced by a series of echoes returning from the organ of interest. Enhancement of this image requires adjustment of the controls on the ultrasound console. Enhancement might require brightening or darkening the entire picture on the screen (turning up or down the overall gain) or increasing or decreasing the gain in the area of interest only (near or far gain). It is helpful to adjust the gain such that a structure known to be anechoic (without echoes), such as blood within the heart or within a blood vessel, looks black to the observer's eye. Adjusting the focus to concentrate on the target area can also be easily accomplished. Because the ultrasound wave becomes attenuated as it passes deep into the tissue, the returning signal from the deepest region may require enhancement by adjusting the time-gain compensation slide pots on the console. Magnification of the image is also possible. Once the desired image is obtained, it can be "frozen" to print or store the image or to perform measurements. Annotation (e.g., labeling) is also performed on the frozen image. The series of images obtained just prior to freezing the image can be reviewed using the cine-loop function in case the frozen image missed the target. The initial images are usually displayed in grayscale (B-mode or brightness modulation), but most machines have both color-flow and Doppler imaging features as well, which can be added during real-time scanning and are essential for vascular procedures.

Traditionally, ultrasound examinations are performed with the patient in a supine position. When the transducer is held in a sagittal orientation (the transducer directional marker

Table 1 Transducers and Their Applications

Transducer Frequency (MHz)	Application
2–3.5	Abdominal Cardiac Obstetrics
5.0	Neonates/pediatrics Peripheral vascular Cerebrovascular Breast Thyroid
10	Vein mapping Soft tissues

toward the patient's head), the left side of the screen is oriented toward the head, with the right side toward the feet. When the marker is turned toward the patient's right for transverse imaging, the patient's right side is on the left side of the screen, and the head would now be toward the top of the screen. Holding transducers incorrectly results in serious errors in interpretation of the images. Other tricks for obtaining the best possible images (in addition to those listed above) include darkening the room as much as possible; sliding, tilting, and rocking the transducer on the skin rather than picking it up and moving it abruptly; using gentle but firm pressure; applying graded compression when air is present; or repositioning the patient if needed. Most importantly, the surgeon sonographer should take his or her time to obtain the best possible images under the circumstances. Rushing through an examination is the most common source of error.

Although ultrasound technology has an excellent safety profile, with the added benefit of high image quality and portability without radiation, there is still the possibility to inflict harm on a patient. Each unit must be well maintained and checked routinely to be sure that the ALARA principle (As Low As Reasonably Achievable) is adhered to, in reference to power and exposure time while obtaining the necessary clinical information. Tissues will heat up during lengthy examinations, and cavitation is also possible if the power is too high. Each transducer should be inspected regularly for breaks in the housing or cable that could potentially produce an electrical shock. After each examination, the transducers should be thoroughly cleaned using a solution recommended by the manufacturer so that blood or fluids are not transmitted from one patient to the next. Surgeons must also be involved in performance improvement programs where diagnostic decisions and procedures performed using ultrasound are reviewed for accuracy and patient safety.

USE OF ULTRASONOGRAPHY IN TRAUMA

The FAST Scan

The use of ultrasonography to query the pericardium and peritoneal cavity for blood has become standard in trauma centers. Referred to as the FAST examination (Focused Assessment for the Sonographic examination of the Trauma patient), it has rapidly replaced diagnostic peritoneal lavage as the preferred method for detecting hemoperitoneum in the unstable patient following blunt trauma.¹ It is also appropriate for pregnant and pediatric patients, for whom radiation exposure is more dangerous. In penetrating trauma, the abdominal portion of the FAST examination is not always helpful, because the amount of intra-abdominal fluid associated with hollow viscous injuries (most likely to be injured in penetrating trauma) is often too small to detect with ultrasonography. On the other hand, a limited echocardiographic examination is extremely sensitive in detecting penetrating injuries to the heart associated with pericardial fluid and has replaced all other noninvasive (e.g., central venous pressure [CVP], serial electrocardiograms) and invasive (i.e., pericardial window) methods of initial evaluation.²

Technique Sonographic detection of pericardial effusion is straightforward, requiring no specialized knowledge of echocardiographic cardiac anatomy. This echocardiographic portion of the FAST examination is performed using a curved

array transducer (2.0–5.0 MHz) with a small footprint held in the subxiphoid position at 30° to the skin and aimed toward the left shoulder [see Figure 1]. Note that for all views, the marker groove points toward the left side of the screen. From this same position, the transducer is rotated transversely, and a four-chamber view can be seen in most patients depending on body habitus. The third view is obtained from the left parasternal area (long axis of the heart) with the transducer oriented along a line between the right shoulder and the left hip. Pleural effusions may be confused with pericardial effusions, but this is minimized in the subcostal view because there is no pleural reflection between the liver and the heart. Additionally, intrapericardial fluid will conform to the contour of the heart. Viewing the heart in more than one plane will also help reduce interpretation errors. Echocardiography can also be used to detect the presence of cardiac motion when no blood pressure is obtainable after trauma (pulseless electrical activity [PEA]). Following penetrating trauma, the detection of PEA may be an indication for emergency department thoracotomy, particularly in the presence of pericardial tamponade.

The abdominal portion of the FAST examination begins in the right upper quadrant with the transducer placed in sagittal orientation along the right anterior midaxillary line between the 11th and 12th ribs. The liver, diaphragm, and right kidney are imaged and, in particular, the Morison pouch (between the kidney and liver) is examined for fluid. In the supine position, this is the most likely spot for fluid or blood to accumulate [see Figure 2]. On the left side, the spleen and left kidney are found in the posterior midaxillary line slightly higher (between the ninth and 10th ribs). Once again, the transducer is oriented in a sagittal plane. It is extremely important to examine not only the space between the spleen and the kidney but also the space between the left hemidiaphragm and the spleen, where many splenic injuries will manifest. Because rib shadows may prevent full visualization of the spleen, having a cooperative patient take a deep breath can be helpful. The final abdominal image is of the pelvis. Here the bladder serves as an acoustic window and must contain fluid to be seen. The transducer is oriented for transverse sections over the pubis, aimed at the feet. If a Foley catheter is in place, fluid should be instilled into the bladder to facilitate detection of pelvic fluid [see Figure 2].

Detection of Hemothorax

Other uses for ultrasonography following injury include scanning for the presence of hemothorax, or pneumothorax, and in serial follow-up of intra-abdominal solid organ injuries being managed conservatively. Surgeons from Emory University were among the first to describe the evaluation of the pleural space using a standard 3.5 MHz transducer in the trauma room as part of the FAST examination.³ Briefly, the transducer is held in the sagittal position and advanced in the midaxillary line from the 10th and 11th intercostal spaces (where the liver, diaphragm, and kidney are seen) cephalad until the supradiaphragmatic space is visualized. Fluid in the pleural space will appear as a black triangle above the hyperechoic (white) diaphragm [see Figure 3]. On the left side, the spleen and kidney are first viewed at approximately the ninth or 10th intercostal space in the posterior axillary line, and the transducer is simply advanced cephalad until the left hemidiaphragm and the supradiaphragmatic space are identified. The 97.5%

(e) Positive echocardiogram showing pericardial fluid.

Figure 2 (a) Transducer position for the right upper quadrant (RUQ) portion of the FAST examination for trauma. (b) Normal RUQ scan showing the liver and kidney. (c) Fluid seen in the Morison pouch in an RUQ scan (arrow). (d) Transducer position for the left upper quadrant (LUQ) portion of the FAST examination for trauma. Note the slightly higher position and more posterior than that for the RUQ.

sensitivity and 99.7% specificity observed for thoracic ultrasonography were similar to those for portable chest x-rays in the trauma bay. The accuracy of this technique was only slightly less when used in the critical care setting to detect pleural effusion (94% accuracy).⁴

Detection of Pneumothorax

Using ultrasonography to detect pneumothorax is slightly more challenging as it requires recognition of the “absence” of the normal findings seen with an expanded lung. To perform this examination, a 3.5 MHz phased array transducer is held in a sagittal orientation in the second intercostal space in the midclavicular line. The examination is performed over several respiratory cycles. A normal lung will demonstrate a “lung-sliding” sign, seen as a to-and-fro motion at the interface between the visceral and parietal pleura with respirations [see Figure 4].

A comet tail artifact, manifested by hyperechoic streaks extending down from the visceral and the parietal pleural interface, is also commonly seen when imaging a normal lung. In the absence of these two findings, a pneumothorax will be present 99% of the time.^{5,6} Visualizing of the lung slide can be enhanced by using a linear array transducer (7.5 MHz) oriented for sagittal sections and applying power color Doppler mode (“power slide”).⁷ Although neither of these methods eliminates completely the need for a chest x-ray, they may be very useful in situations such as the operating room, the intensive care unit (ICU), or an austere environment when an x-ray is delayed or unavailable.

Evaluation of Patients with Solid Organ Injuries

The treatment of a stable patient with a solid organ injury (liver, spleen, kidney) identified on a computed tomographic

Figure 2 (e) Normal LUQ view showing the spleen and kidney. (f) Positive LUQ scan showing fluid around the spleen (arrow). (g) Transducer position for a pelvic image of the FAST examination (sitting on the pubic bone and aimed toward the feet). (h) Fluid in the pelvis using a full bladder as the acoustic window.

(CT) scan is most often observational. However, the need for follow-up imaging to identify patients whose injuries have progressed and/or those who have developed complications is controversial. Abdominal CT scanning, although extremely accurate, is expensive and delivers additional radiation (of particular concern in the management of pediatric trauma). We hypothesized that surgeon sonographers could successfully follow these injuries using ultrasonography. The surgeons involved in our study had considerable training and experience in performing ultrasound examinations, but we were only able to visualize the actual organ injury approximately one third of the time.⁸ However, we successfully detected 13 of the 15 complications, including intra-abdominal abscesses, arterial pseudoaneurysms, and bilomas. More importantly, we were able to assess the amount of hemoperitoneum present during serial examinations and thus determine more accurately than by following hematocrits that patients were still bleeding.

USE OF ULTRASONOGRAPHY IN THE SURGICAL ICU

Central Line Placement Using Ultrasound Guidance

In the United States, an estimated 5 million central venous catheters are inserted annually for the purposes of monitoring hemodynamic variables, administering fluids and medications, or providing parenteral nutrition.⁹ Unfortunately, the use of central venous catheters is associated with a number of complications, which are both hazardous for the patient and expensive to treat. Mechanical complications occur in 5 to 19% of patients, infectious complications in 5 to 26%, and thrombotic events in 2 to 26%. Using ultrasound guidance during insertion of an internal jugular (IJ) catheter has been demonstrated to reduce the time required for insertion, the rates of unsuccessful attempts, and the number of carotid artery punctures. A recent meta-analysis of 18 trials concluded that the use of ultrasonography to place central lines resulted in a significant reduction

Figure 3 (a) Normal ultrasound view of the pleural space (arrow at diaphragm). (b) Ultrasound view of a hemothorax (arrow).

Figure 4 (a) A 7.5 MHz transducer in the second intercostal space for evaluation of a potential pneumothorax. (b) Normal lung markings. Note the “comet tail” effect from a normal air artifact. The interface between the parietal and visceral pleura is marked with the upper arrow (point of observation for the “lung slide”).

in failure rates (risk difference -12 , 95% confidence interval [CI] -0.18 to -0.06), the number of attempts (risk reduction 1.41 , 95% CI 1.15 to 1.67), and arterial puncture rates (risk difference -0.07 , 95% CI -0.10 to -0.03).¹⁰ Ultrasonography improved outcomes most convincingly for IJ vein cannulation (as opposed to the subclavian vein) and when used by clinicians less experienced at line placement. Karakitsos and colleagues performed a prospective comparison of the landmark technique versus real-time ultrasound-guided catheterization of the IJ veins in critically ill patients.¹¹ This randomized study included 450 patients in each of the two study arms. There were no significant differences between the two groups in gender, body mass index, previous catheterization, skeletal deformities, or other factors that could make line placement difficult. The clinicians involved in the study had considerable experience in inserting central lines (10 years on average). Cannulation of the IJ vein was accomplished in all 450 patients

using ultrasound guidance versus 425 patients using surface landmark techniques ($p < .001$). The time for line placement and the number of attempts were also significantly reduced in the ultrasound group. In the landmark group, hematoma formation occurred in 8.4%, hemothorax in 1.7%, pneumothorax in 2.4%, and central venous catheter-associated bloodstream infection in 18%, which were all significantly more common than in the ultrasound group ($p < .001$).

Technique of Placing an IJ Catheter Under Ultrasound Guidance

- Step 1:** Assemble the equipment listed in Table 2.
- Step 2:** Don personal protective gear and a sterile gown and gloves.
- Step 3:** Place the patient in the head-down position if possible.

Table 2 Equipment Needed for Central Line Placement

Standard commercial central catheter insertion kit
Large barrier drape
Sterile gown/gloves
Mask, eyewear, hat (personal protective gear)
7.5 linear array transducer connected to standard ultrasound unit
Sterile conduction gel
Sterile plastic sheath/probe cover

- Step 4:** Standing at the head of the bed, identify the relevant surface anatomy: the mastoid process, clavicle, and clavicular and sternal heads of the sternocleidomastoid muscle.
- Step 5:** Prepare the area widely with chlorhexidine and drape widely.
- Step 6:** Insert the ultrasound transducer into the sterile sheath after placing conduction gel into the bottom of the probe cover.
- Step 7:** Place a small amount of sterile conduction gel on the skin surface at the junction of the two heads of the sternocleidomastoid muscle.
- Step 8:** Holding the transducer parallel to and just above the clavicle, locate the IJ vein. It will be larger and flatter than the adjacent carotid artery, which is located medial to the vein [see Figure 5a]. A patent IJ vein should be compressible if it does not contain thrombus. Rarely, color flow or Doppler applications may be needed. Once the vein is located, orient the probe so that the vein appears on the right side of the screen (for right IJ vein cannulation) or on the left side of the screen if the left IJ vein is used. This will minimize confusion during the procedure.
- Step 9:** Continue to visualize the vein holding the transducer with one hand while introducing the needle with the other hand. The direction of the needle must be at right angles to the middle of the transducer and at an angle of 45° to the skin [see Figure 5b].
- Step 10:** Once the needle is seen to enter the vein, aspirate back with a syringe to confirm free venous flow [see Figures 5c to 5e].
- Step 11:** Pass the guide wire through the needle, monitoring for any cardiac arrhythmias (should they occur, pull the guide wire back). The needle can now be withdrawn from the vein, leaving the wire intact.
- Step 12:** Using a blade, make a small skin incision at the entrance of the wire and pass the catheter-dilator assembly over the wire into the vein. The catheter can also be visualized by ultrasonography.
- Step 13:** Remove the dilator and wire together, then use a syringe to aspirate air from the catheter, confirm venous return, and demonstrate that fluid can be infused without excessive pressure.
- Step 14:** Suture the catheter securely in place.
- Step 15:** Confirm the position with x-ray.

Complications associated with placement of an IJ catheter The most common immediate complications of

central venous catheter placement are arterial puncture, hematoma formation, and pneumothorax. A chest radiograph should be obtained immediately after any central venous catheterization attempt to evaluate for pneumothorax and to confirm proper catheter position prior to its use. Arterial puncture, which occurs in 6 to 9% of attempts, is more common with IJ line placement than with subclavian catheterization. If arterial puncture is recognized at the time of needle placement, it is managed by withdrawing the needle and maintaining gentle pressure over the artery for several minutes while observing for hematoma formation. If the injury is recognized after the dilator is in place, it should be left in place and a vascular surgeon consulted; removal of the catheter may require endovascular stenting or suture closure of the carotid artery. Pneumothorax (incidence of 0.2 to 1% with IJ catheters) is slightly less likely than with subclavian lines and is generally caused by advancing the needle too far in search of the vein instead of withdrawing to reassess the position and course of the needle. Small pneumothoraces (< 10%) may be observed and reevaluated with chest imaging 6 hours later; larger or symptomatic pneumothoraces require tube thoracostomy.

Assessment of Volume Status in the ICU with Ultrasound Techniques

Surgeons are beginning to use bedside ultrasonography to assess cardiac function and to estimate volume status in the ICU. One simple measure is to note the relative collapse of the right ventricle in a patient who is volume depleted. Another method is to measure the diameter of the inferior vena cava (IVC) during resuscitation. Using a standard abdominal transducer held for sagittal scanning, the anteroposterior diameter of the IVC can be measured just below the diaphragm in the hepatic segment.¹² Given that the diameter will change with respiration, it should be measured in both phases. A second measurement is taken in a transverse orientation [see Figure 6]. Yanagawa noted that the IVC diameter was significantly smaller (average 6.5 mm) in patients who became hypotensive again after an initial response to fluid resuscitation (so-called transient responders) as opposed to stabilized patients, in whom the IVC diameter averaged 10.7 mm.¹² In a more advanced study, Gunst and colleagues measured both stroke volume and IVC diameter using ultrasonography and compared their estimates of cardiac index based on ultrasound data compared with the results found with more directly measured indices using pulmonary artery catheterization.¹³ These surgeons were very accurate in estimating cardiac index and CVP; however, each of these investigators had completed 2 days of focused cardiac ultrasound training and had 5 to 15 years of ultrasound training prior to participating in this study. Nonetheless, it is clear that the utility of bedside ultrasonography in estimating volume status will continue to expand in the near future.

Ultrasound-guided Thoracentesis

Pleural effusions can be easily diagnosed and aspirated under ultrasound guidance in the ICU.¹⁴ In one recent study of ultrasound-guided thoracentesis in patients receiving mechanical ventilation, pneumothorax occurred in only 1.3% of the 232 patients who underwent this procedure.¹⁵ Pigtail catheters can

Standard central line insertion kit
Large barrier drape
Sterile gown/gloves
Mask, eyewear, hat (personal protective gear)
Caldwell needle (15 gauge)
Sterile extension tubing
Syringe
Scalpel
Local anesthetic

also be inserted using ultrasonography.¹⁶ The equipment needed for these procedures is outlined in Table 3.

Technique for Performing Ultrasound-Guided Thoracentesis

- Step 1:** Position the patient either in the lateral decubitus (the affected side up) or the supine position. Elevation of the head of the bed may also be useful.
- Step 2:** Perform the ultrasound examination (using a 3.5 MHz convex transducer) to locate the diaphragm, liver (or spleen), and targeted pleural fluid.
- Step 3:** If possible, switch to a 7.5 MHz linear probe to visualize the ribs and vascular structures within the chest.
- Step 4:** Choose a puncture site allowing at least one rib space of fluid above and below.
- Step 5:** Mark the site, prepare the chest, and then inject the area generously with local anesthesia, including the pleural surface.
- Step 6:** Insert a 18- to 20-gauge sheath needle into the targeted area, confirming the location of the needle with ultrasonography, and perform the aspiration.
- Step 7:** Once the fluid has been completely removed, withdraw the needle while applying constant negative pressure to minimize the chance of pneumothorax.

- Step 8:** If prolonged drainage is necessary, a larger catheter can be advanced into this area using the Seldinger technique, attaching the catheter to a water-sealed drainage system.¹⁷

Ultrasound and Paracentesis

Paracentesis is another useful technique that is also made safer under ultrasound guidance. In the ICU, paracentesis can be used to sample abdominal fluid for diagnosis (blood, intestinal contents, infection) or as a method of relieving pressure (ascites or secondary intra-abdominal hypertension following burns or overzealous resuscitation). The right and left lower quadrants are the most dependent locations and the easiest to access (generally above and medial to the superior iliac spine). Safe entry points for paracentesis that avoid the inferior epigastric vessels were mapped out recently by Saber and colleagues.¹⁸

Technique for Performing Ultrasound-Guided Paracentesis

- Step 1:** Assemble the equipment listed in Table 3.
- Step 2:** The abdomen is scanned using a 3.5 MHz curved array transducer to locate the fluid collection(s).
- Step 3:** Place the patient in a supine position of comfort.
- Step 4:** Don personal protective gear, including a gown and gloves.
- Step 5:** Scrub the anterior abdominal wall with chlorhexidine solution and drape the region.
- Step 6:** Infiltrate the skin of the intended puncture site with local anesthetic.
- Step 7:** Use the scalpel to make a nick in the skin to allow passage of the needle.
- Step 8:** Advance the Caldwell needle through the abdominal wall while aspirating with a syringe (note: ultrasonography can be used to guide the needle into the fluid collection).
- Step 9:** Once fluid is seen to enter the syringe, stop advancing the needle. The drainage catheter should be advanced over the needle into the fluid and the needle removed.

Step 10: If prolonged drainage is required (as with tense ascites), the catheter can be attached to a collection canister.

Step 11: Observe the wound for ascetic leak and/or the development of a hematoma, and then dress it with a transparent dressing.

Complications of thoracentesis and paracentesis

The principal complications of thoracentesis are pneumothorax and hemothorax. Drainage of very large effusions may also lead to reexpansion pulmonary edema, although this is a rare entity. In one recent study of ultrasound-guided thoracentesis in patients receiving mechanical ventilation, pneumothorax occurred in only 1.3% of the 232 patients who underwent this procedure.¹⁵ As noted above with IJ cannulation, small pneumothoraces may be observed, but larger (> 10%) or symptomatic cases require tube thoracostomy. Hemothorax complicating thoracentesis is particularly troubling because it suggests injury to an intercostal vessel, which may bleed significantly and potentially require operative ligation. A routine chest radiograph should be obtained following the procedure, and attention should be paid to significant hematoma or oozing from the puncture site.

Paracentesis may be complicated by abdominal wall hemorrhage and by hemodynamic instability resulting from fluid shifts. Large-volume paracentesis leads to fluid and protein losses with accompanying hypovolemia, hypotension, and even acute renal insufficiency. Empiric replacement of proteinaceous solute by infusion of salt-poor albumin is generally practiced (50 mL of 25% albumin for each liter of ascites drained). If the puncture site is not carefully selected, inferior epigastric vessel injury may occur, leading to expanding abdominal wall hematoma and/or hemoperitoneum. If this occurs and the hematoma does not tamponade the bleeding, exposure and ligation of the vessels will be necessary.

Detection of Venous Thrombosis with Duplex Ultrasonography

Critically ill and injured patients are at high risk for potentially lethal venous thromboembolism. Unfortunately, the current methods of venous thromboembolism prophylaxis are often contraindicated in the patients who are at greatest risk, and surveillance for deep vein thrombosis (DVT) is frequently used even in the absence of symptoms. Additionally, an immediate DVT scan can be helpful when pulmonary embolism is suspected in ICU patients. The sensitivity and specificity for duplex ultrasonography in symptomatic patients are very high, and this study has now replaced venography as the primary imaging procedure for the detection of DVT. Compressibility under probe pressure is the most accurate test, reaching 97 to 100% sensitivity and 99% specificity for the diagnosis of femoral and popliteal DVT.¹⁹ In contrast, the visibility of the thrombus as a fixed, echogenic image within the lumen has a sensitivity of only 50%. DVT should also be suspected when there is a lack of augmentation of flow above the area being compressed. As with any ultrasound examination, the accuracy is highly dependent on the expertise of the examiner, and we do not mean to imply that surgeons will have the same excellent results as registered vascular technicians. However, focused venous ultrasound examinations should be within the skill set of a general surgeon.

Technique for Performing a Venous Ultrasound Examination

Step 1: Position the patient in a supine and reversed Trendelenburg position (if possible), with the leg abducted and externally rotated and the knee flexed.

Step 2: Using a 7.5 MHz linear transducer held in a transverse position, identify the common femoral vein and artery at the level of the inguinal ligament.

Step 3: The initial imaging should be done using the B-mode (grayscale).

Step 4: Focusing on the vein, apply pressure until the vein collapses. Follow the vein down in a transverse plane, using serial compression applied at 1 to 2 cm intervals.

Step 5: The vein will dive deep above the knee but can be visualized again posterior to the knee.

Step 6: Although the hallmark of DVT is a lack of compressibility, occasionally, a thrombus will be visible within the lumen [see Figure 7].

Step 7: Flow can be visualized within the vein by applying color and Doppler imaging. With the transducer still in a transverse orientation, find the common femoral vein or artery and apply color flow. Keeping the vein in view, orient the transducer for longitudinal imaging. Once flow is visualized in the thigh, squeezing the calf muscles should increase the flow signal. Clinically significant DVT below the level of the thigh is unlikely if augmentation is present.

Step 8: Repeat these same steps on the opposite side and compare images and results.

Other Bedside Procedures

PERCUTANEOUS TRACHEOSTOMY

Operative tracheostomy has been performed for several centuries, and the typical modern technique was standardized by Jackson in 1909. A percutaneous Seldinger technique was developed in the 1980s by Ciaglia and colleagues and has gained popularity in recent years because of its suitability for performance at the bedside.²⁰ Use of videobronchoscopic guidance has reduced immediate complications, but it should be recognized that operative (“open”) tracheostomy remains the gold standard as it allows for more control and has lower rates of long-term complications, such as subglottic stenosis.^{21,22}

Indications for tracheostomy include orofacial trauma, resection of head or neck malignancy, and the need for prolonged mechanical ventilation. The timing of tracheostomy in critically ill patients has long been debated, and ongoing clinical trials strive to determine the optimal timing. The basic principle is to perform the procedure early enough to facilitate subacute care and reduce oropharyngeal, sinus, and pulmonary complications; however, performing tracheostomy too early in a course of mechanical ventilation will lead to unnecessary procedures on those patients who were nearing extubation at the time of operation. The TracMan clinical trial conducted at Oxford University randomized over 900 critically ill patients to early (days 1 to 4) versus late (day 10 or later) tracheostomy. This represents the largest coordinated effort yet to determine the optimal timing of tracheostomy; recruitment completed in December 2008, and the results are expected to be reported in 2009.²³

Figure 7 Ultrasound image of a femoral vein deep vein thrombosis (*markers*).

Tracheostomy is a clean-contaminated operation because the respiratory tract is entered. These wounds are far from sterile as there is considerable contamination by respiratory secretions and saliva. However, infections are infrequent, and there is no role for prolonged courses of antibiotic therapy beyond a single preincision dose, as is the general recommendation for clean-contaminated operations.

Technique for Percutaneous Tracheostomy

- Step 1:* Assemble the equipment listed in Table 4.
- Step 2:* Position the patient so as to slightly raise the shoulder off the bed and extend the neck.
- Step 3:* Don personal protective gear, including a sterile gown and gloves.
- Step 4:* Scrub the anterior neck from the chin to the sternal notch with chlorhexidine solution and place sterile drapes.
- Step 5:* Ask the bronchoscopist to advance the scope down the endotracheal tube and visualize the carina and then withdraw the scope to a position

a centimeter below the vocal folds. Maintain this endoluminal view of the trachea.

Table 4 Equipment Needed for Percutaneous Tracheostomy

Large barrier drape
Sterile gown/gloves
Mask, eyewear, hat (personal protective gear)
Bronchoscope
Laryngoscope and endotracheal tube
Tracheostomy tube (at least two sizes)
Seldinger tracheostomy kit with dilator
Skin suture and needle holder
Ventilator tubing adapter for bronchoscope and accordion extension for tracheostomy
Scalpel
Syringe

- Step 6:* Withdraw the endotracheal tube so that the tip is repositioned just distal to the bronchoscope tip.
- Step 7:* Identify a point in the midline of the anterior neck, midway between the cricothyroid membrane and sternal notch. Apply local anesthetic to this site and then use an 18-gauge needle attached to a 10 mL syringe to puncture the trachea. It is critical that the puncture be visualized by the bronchoscope and be in the midline of the anterior trachea and not too close to the cricothyroid cartilage [see Figure 8].
- Step 8:* Pass the guide wire through the needle into the trachea and remove the needle.
- Step 9:* Make a 2 cm transverse skin incision centered on the wire. Do not cut deep to the skin as bleeding from the thyroid or thyroid vessels can be problematic and require operative repair.
- Step 10:* Apply generous sterile lubricant to the assembled tracheostomy tube–dilator device, then pass it over the wire and twist it while pushing posteriorly to dilate the tracheal puncture site and pass the tracheostomy tube. Once in the trachea (visualized by the bronchoscope), immediately remove the dilator while holding the tracheostomy tube in place.
- Step 11:* Confirm proper ventilation through the tracheostomy tube and then remove the endotracheal tube.
- Step 12:* Suture the faceplate of the tracheostomy tube to the adjacent skin and further secure it with a necklace-type tie around the neck.

- Step 13:* Remove instruments for reprocessing and dispose of sharp waste.

Complications of percutaneous tracheostomy

Following tracheostomy, patients should initially be cared for in an ICU owing to the potential severity of complications. The site should be observed for bleeding, cellulitis, or development of subcutaneous emphysema. Dislodgment or misplacement of the tracheostomy tube must be immediately corrected as this will lead to death in short order. If possible, the tube should be reinserted, but often the safest approach is to resecure the airway by orotracheal intubation and then convert to a formal (“open”) tracheostomy in the operating room. Significant bleeding around the tracheostomy tube usually signifies injury to the thyroid parenchyma or one of its vessels; if this does not abate with hematoma tamponade in a matter of minutes, this, too, requires operative intervention.

A first tracheostomy tube change should be avoided at all costs during the first 10 days as there is the potential for fatal airway loss. Even after 10 days, any tracheostomy tube change should be performed with airway rescue equipment and supplemental oxygen available, an informed nurse at the bedside to assist as needed, knowledge of the patient’s native anatomy by the surgeon (i.e., is the larynx patent, thus permitting orotracheal intubation), and a spare tracheostomy tube one size smaller than the one in the patient’s airway. The presence of a respiratory therapist is encouraged, especially for the first change.

Figure 8 Anatomic land markings of the neck. V = thyroid notch; box at the cricothyroid membrane; broken line at the thyroid isthmus; solid line at the first tracheal ring; curved line at the sternal notch.

TUBE THORACOSTOMY

Thoracostomy tubes (“chest drains” or “chest tubes”) are placed to evacuate air or fluid in the pleural space and have become a primary treatment modality for pleural disease since first described by Hewett in 1876. Pneumothorax may occur spontaneously, following injury, or as the result of instrumentation, such as with percutaneous biopsy or thoracentesis. Pneumothoraces can be treated with standard chest tubes (of any size) or with pigtail catheters inserted using a Seldinger technique. Fluid can accumulate in the pleural space as a result of many different processes, including trauma, pneumonia, malignancy, and congestive cardiac disease. Drains placed for simple fluid may be of smaller caliber, but those placed for hemothorax should be larger to prevent blockage by coagula (typically 36 French for adults).

All hemothoraces should be promptly drained to prevent fibrothorax and possible trapped lung. Failure to promptly drain blood in the pleural space will render this technique ineffective, and formal decortications (i.e., via video-assisted thoracic surgery) will be required. Other fluid collections should be drained and the underlying pathology addressed to prevent recurrent accumulation. Special caution should be taken when addressing malignant effusions because these have a tendency to reaccumulate after drain removal. If the underlying disease is not going to be treated, the patient should generally either be treated with pleurodesis (to obliterate the pleural space and prevent recurrence) or placement of a chronic, tunneled pleural drain.²⁴

These chest procedures must always be performed in as sterile a fashion as possible, although the immediacy of tension physiology may sometimes require the surgeon to forgo

fastidious draping. It remains unclear whether presumptive or prophylactic antibiotics prevent empyema related to chest drain placement. Although the answer remains unclear, a recent multicenter trial in trauma patients failed to demonstrate a benefit of antibiotic administration.²⁵ If antibiotics are administered, they should be given prior to beginning the procedure and be limited to one dose of a first-generation cephalosporin.

Technique for Tube Thoracostomy

- Step 1:** Assemble the equipment listed in Table 5. If the patient is stable, consider administering an intravenous narcotic.
- Step 2:** Position the patient with the affected side tilted up and the ipsilateral arm raised above the head [see Figure 9].

Table 5 Equipment Needed for Tube Thoracostomy

Large barrier drape
Sterile gown/gloves
Mask, eyewear, hat (personal protective gear)
Standard commercial central catheter insertion kit
Suitably sized chest tube
Scalpel, large hemostat, needle driver
Heavy silk or nylon suture
Local anesthetic
Drain trap/suction regulator
Occlusive dressing

Figure 9 Correct position for placement of a chest tube. Note that the tube is directed posterior and cephalad and the right arm is raised above the head.

- Step 3:* Don personal protective gear, including a sterile gown and gloves.
- Step 4:* Scrub the anterolateral chest wall with chlorhexidine solution and drape the region.
- Step 5:* Palpate the chest wall to identify an intercostal space around the fifth rib. In men, the nipple is a useful surface landmark to indicate the height of the dome of the diaphragm, below which one should generally not stray.
- Step 6:* Infiltrate the skin with local anesthetic and make a skin incision at the interspace below the intended thoracostomy site. Bluntly separate the subcutaneous tissue and overlying muscle to arrive at the rib and intercostal musculature. Infiltration of local anesthetic in the periosteum and pleura is a useful but often ignored step.
- Step 7:* Blunt spreading over the top of a rib allows puncture through the pleura into the intercostal space, after which the tube can be slid in while pointing it superiorly and posteriorly. Creation of a proper subcutaneous tract and direction of the tube toward the thoracic apex decrease the likelihood of the tube entering a pulmonary fissure.
- Step 8:* Secure the tube to the adjacent skin with a heavy suture of silk or nylon.
- Step 9:* Connect the tube to the drain trap–suction device and apply an occlusive dressing.
- Step 10:* Remove instruments for reprocessing and dispose of sharp waste.

For a visual reference, readers are referred to the video featured in the *New England Journal of Medicine*.²⁶

Traditionally, all chest drains were initially placed to suction (20 cm water) and subsequently transitioned to water seal (a one-way safety valve with no applied suction) as the volume of output decreased. For many chest tube indications, a growing body of evidence supports placement of chest drains to water seal from the outset. This has been demonstrated to accelerate the resolution of air leaks and duration of chest tubes.²⁷

Complications of tube thoracostomy The most common immediate complication of this procedure is a malpositioned tube, whether in an interlobar fissure, occluded by a kink, or even placed completely within the chest wall rather than the pleural space. A chest radiograph should be obtained after the placement of any chest drain to verify tube position and to determine if the pleural air or fluid is beginning to drain properly. Inadequate tube position may sometimes be addressed by sterile withdrawal and resuturing, but once a tube has been placed, it should never be advanced. Much more rarely, tube placement may cause injury to the pulmonary parenchyma or bleeding from an intercostal or pulmonary vessel. The latter should be suspected with persistent voluminous bloody output and/or any hemodynamic instability after tube placement. Such vascular injuries require operative intervention for definitive control.

Removal of chest tubes should be done with care not to allow air to entrain into the pleural space. This is primarily accomplished by maintaining an occlusive dressing over the tube site and asking the patient to cooperate with tube

removal. Some prefer tube removal during forced expiration to increase intrapleural pressure and thus decrease the risk of recurrent pneumothorax. With this approach, however, some patients suddenly gasp with surprise or pain, suddenly dropping the intrapleural pressure and potentially drawing air in through the tube tract. Another school of thought is to remove the tube while the patient maintains maximal inspiration.

Principles and Process of Documenting Competency in Surgical Skills

Although documenting knowledge in surgery has been standardized by the American Board of Surgery, demonstration of skills has not as yet become part of the certification process. How one acquires, practices, and perfects a surgical skill is an area of great interest to educators and the public alike. Although, certainly, the time spent learning and practicing will vary with the task, with each new skill, the essentials include the following:

1. A period of didactic, hands-on instruction by an expert
2. A period of practice, often while being mentored
3. Demonstration of acquisition of the skill
4. Continued practice-based learning including participation in performance improvement programs and continued education

The Surgical Institutes, currently being developed through the Education Division of the American College of Surgeons (ACS), will form the basis for development of a standard curriculum (including skills training) for each level of residency. Another group that has been very proactive in this arena is the Society of Gastrointestinal Surgeons (SAGES), which has developed and propagated the “Fundamentals of Laparoscopic Surgery” course. In ultrasonography, the ACS Ultrasound Education Committee has developed a series of courses including Level I certification (attendance at the course), Level II certification (passing a skill set), and Level III certification (acquisition of skills under proctorship until reaching the expert or instructor level). In particular, the skills-oriented postgraduate course “Ultrasound in the Surgical ICU” is an excellent model for introducing bedside ultrasound techniques. Once learned, how many examinations are necessary before proficiency is attained is unclear but certainly varies with the nature of the examination. In trauma, 25 FAST examinations performed under supervision is generally considered adequate, although it is important that some of those examinations include patients with positive findings. The American Society of Breast Surgeons requires at least 100 breast ultrasound examinations prior to applying for credentialing. There has been limited success in using simulators to introduce ultrasound skills.²⁸ Recently, Hutton and Wong documented improvement in placement of chest tubes by junior house staff after practicing on a patient simulator.²⁹ A recent systematic review concluded that simulation-based training seems to be transferable to the operating room.³⁰ In this era of decreased time spent in training, surgical educators are challenged to develop more efficient methods of ensuring that general surgeons have acquired competency in both operative and bedside skills, with patient safety and satisfaction as the ultimate measures of success.

Financial Disclosures: None Reported.

1 PREVENTION OF POSTOPERATIVE INFECTION

Jonathan L. Meakins, MD, DSc, FACS

Epidemiology of Surgical Site Infection

Historically, the control of wound infection depended on antiseptic and aseptic techniques directed at coping with the infecting organism. In the 19th century and the early part of the 20th century, wound infections had devastating consequences and a measurable mortality. Even in the 1960s, before the correct use of antibiotics and the advent of modern preoperative and postoperative care, as much as one quarter of a surgical ward might have been occupied by patients with wound complications. As a result, wound management, in itself, became an important component of ward care and of medical education. It is fortunate that many factors have intervened so that the so-called wound rounds have become a practice of the past. The epidemiology of wound infection has changed as surgeons have learned to control bacteria and the inoculum and to focus increasingly on the patient (the host) for measures that will continue to provide improved results.

The following three factors are the determinants of any infectious process¹:

1. The infecting organism (in surgical patients, usually bacteria)
2. The environment in which the infection takes place (the local response)
3. The host defense mechanisms, which deal systemically with the infectious process

Wounds are particularly appropriate for analysis of infection with respect to these three determinants. Because many components of the bacterial contribution to wound infection now are clearly understood and measures to control bacteria have been implemented, the host factors become more apparent. In addition, interactions between the three determinants play a critical role, and with limited exceptions (e.g., massive contamination), few infections will be the result of only one factor [see Figure 1].

Definition of Surgical Site Infection

Wound infections have traditionally been thought of as infections in a surgical wound occurring between the skin and the deep soft tissues—a view that fails to consider the operative site as a whole. As prevention of these wound infections has become more effective, it has become apparent that definitions of operation-related infection must take the entire operative field into account; obvious examples include sternal and mediastinal infections, vascular graft infections, and infections associated with implants (if occurring within 1 year of the procedure and apparently related to it). Accordingly, the Centers for Disease Control and Prevention currently prefers to use the term *surgical site infection* (SSI). SSIs can be

Figure 1 In a homeostatic, normal state, the determinants of any infectious process—bacteria, the surgical site, and host defense mechanisms (represented by three circles)—intersect at a point indicating zero probability of sepsis.

classified into three categories: superficial incisional SSIs (involving only skin and subcutaneous tissue), deep incisional SSIs (involving deep soft tissue), and organ or space SSIs (involving anatomic areas other than the incision itself that are opened or manipulated in the course of the procedure) [see Figure 2].^{2,3}

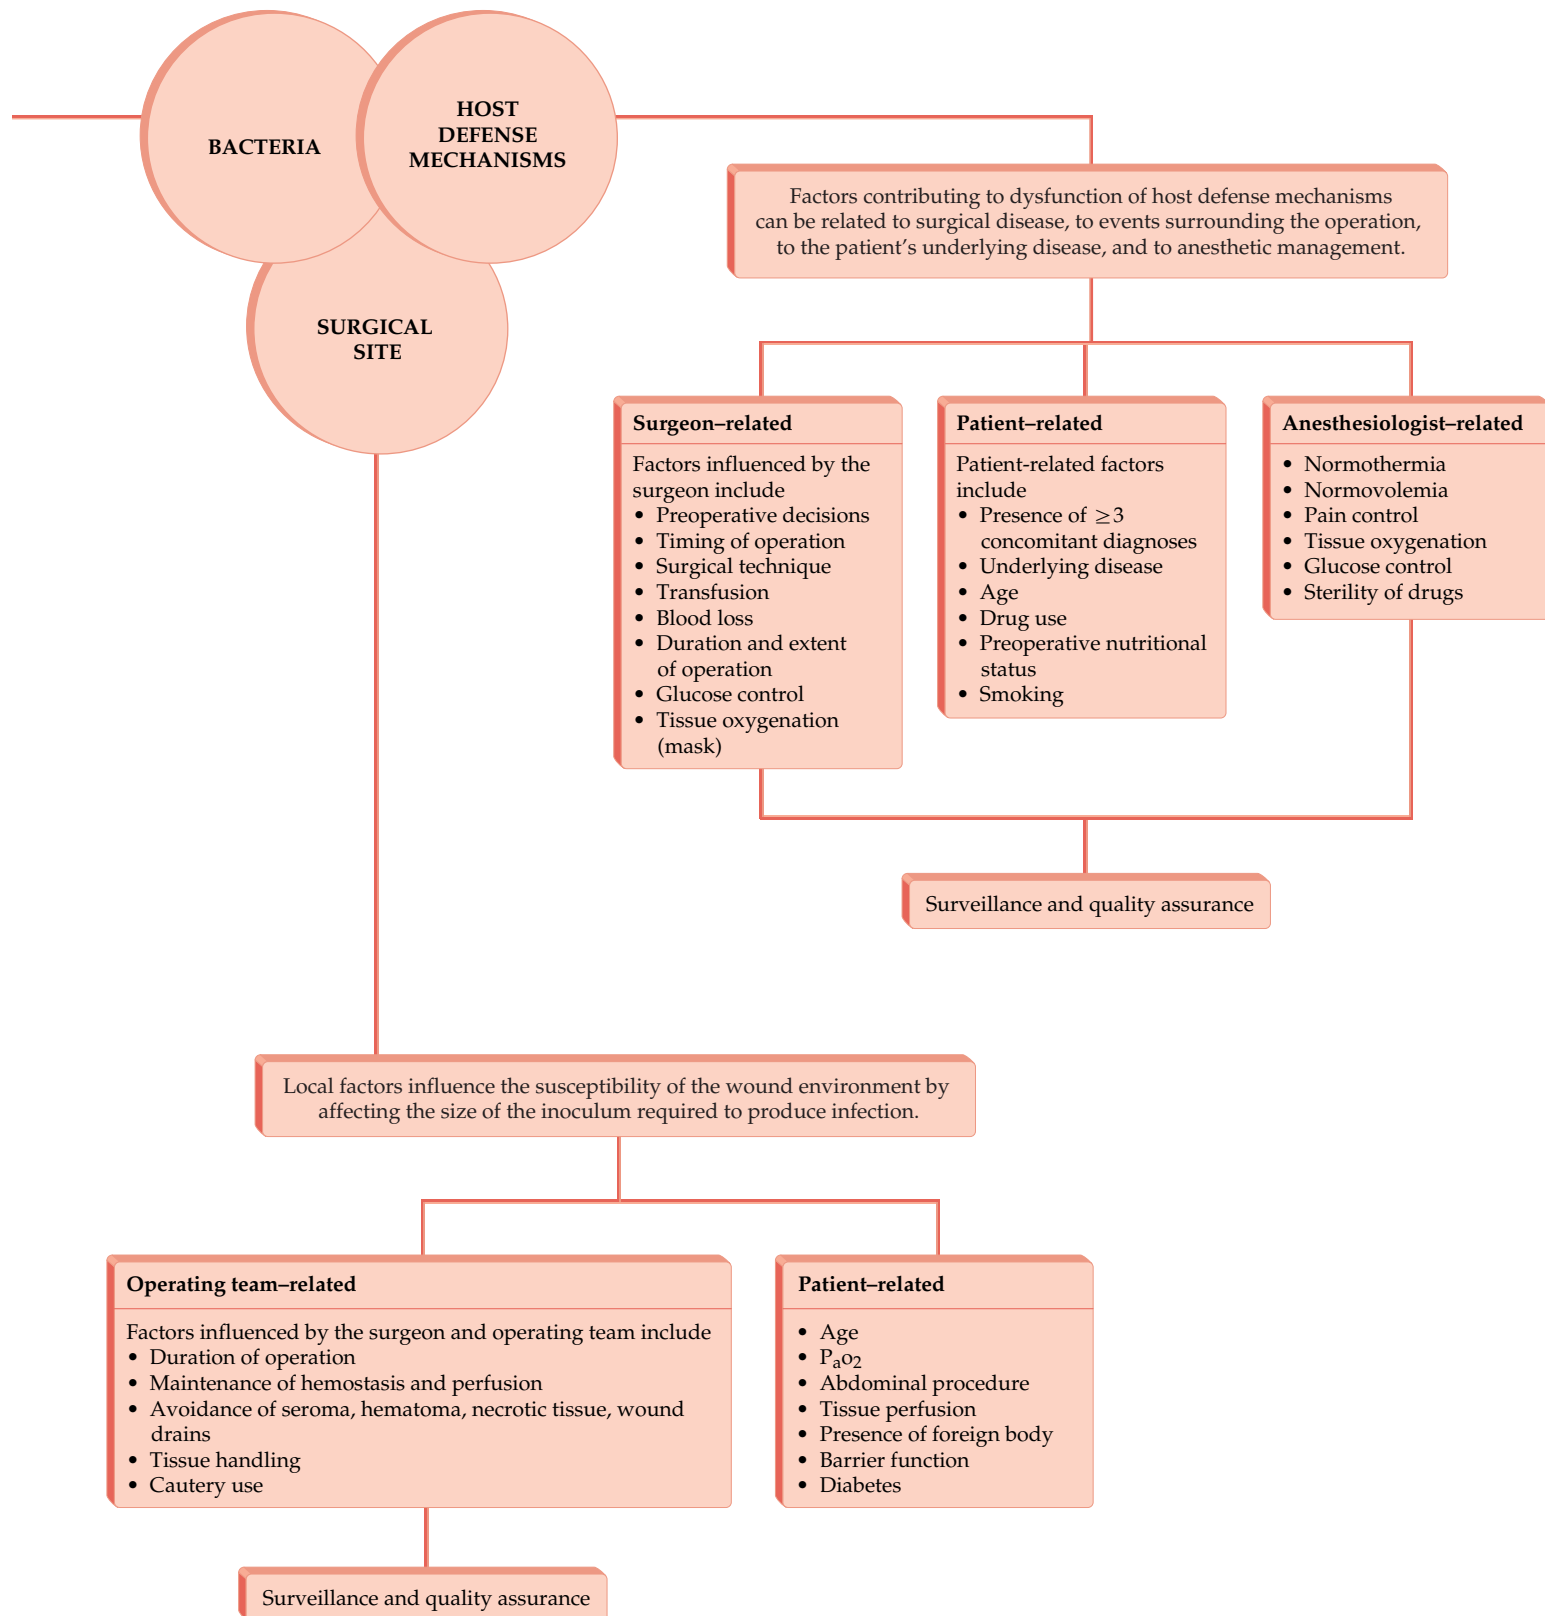

Figure 2 Surgical site infections (SSI) are classified into three categories, depending on which anatomic areas are affected.³

Epidemiology of Surgical Site Infection

Standardization in reporting will permit more effective surveillance and improve results, as well as offer a painless way of achieving quality assurance. The natural tendency to deny that a surgical site has become infected contributes to the difficulty of defining SSI in a way that is both accurate and acceptable to surgeons. The surgical view of SSI recalls one judge's (probably apocryphal) remark about pornography: "It is hard to define, but I know it when I see it." SSIs are usually easy to identify. Nevertheless, there is a critical need for definitions of SSI that can be applied in different institutions for use as performance indicators.⁴ The criteria on which such definitions must be based are more detailed than the simple apocryphal remark just cited; they are outlined more fully elsewhere [see 1:8 *Preparation of the Operating Room*].

STRATIFICATION OF RISK FOR SSI

The National Academy of Sciences–National Research Council classification of wounds [see *Table 1*], published in 1964, was a landmark in the field.⁵ This report provided incontrovertible data to show that wounds could be classified as a function of probability of bacterial contamination (usually endogenous) in a consistent manner. Thus, wound infection rates could be validly compared from month to month, between services, and between hospitals. As surgery became more complex in the following decades, however, antibiotic use became more standardized and other risk variables began to assume greater prominence. In the early 1980s, the Study on the Efficacy of Nosocomial Infection Control (SENIC) identified three risk factors in addition to wound class: location of the operation (abdomen or chest),

duration of the operation, and patient clinical status (three or more diagnoses on discharge).⁶ The National Nosocomial Infection Surveillance (NNIS) study reduced these four risk factors to three: wound classification, duration of the operation, and American Society of Anesthesiologists (ASA) class III, IV, or V.^{7,8} Both risk assessments integrate the three determinants of infection: bacteria (wound class), local environment (duration), and systemic host defenses (one definition of patient health status), and they have been shown to be applicable outside the United States.⁹ However, the SENIC and NNIS assessments do not integrate other known risk variables, such as smoking, tissue oxygen tension, glucose control, shock, and maintenance of normothermia, all of which are relevant for clinicians (although they are often hard to monitor and to fit into a manageable risk assessment). In addition, they do not incorporate a variety of other host variables or operation characteristics derived from the Patient Safety in Surgery Study/National Surgical Quality Improvement Program (NSQIP). These give high, medium, and low probabilities of SSI, which appear to be more accurate but more complex to ascertain than NNIS prediction [see *Integration of Determinants below*].¹⁰

Bacteria

Clearly, without an infecting agent, no infection will result. Accordingly, most of what is known about bacteria is put to use in major efforts directed at reducing their numbers by means of asepsis and antisepsis. The principal concept is based on the size of the bacterial inoculum.

Wounds are traditionally classified according to whether the wound inoculum of bacteria is likely to be large enough to overwhelm local and systemic host defense mechanisms and produce an infection [see *Table 1*]. One study showed that the most important factor in the development of a wound infection was the number of bacteria present in the wound at the end of an operative procedure.¹¹ Another quantitated this relation and provided insight into how local environmental factors might be integrated into an understanding of the problem [see *Figure 3*].¹² In the years before prophylactic antibiotics, as well as during the early phases of their use, there was a very clear relation between the classification of the operation (which is related to the probability of a significant inoculum) and the rate of wound infection.^{5,13} This relation is now less dominant than it once was; therefore, other factors have come to play a significant role.^{6,14}

CONTROL OF SOURCES OF BACTERIA

Endogenous bacteria are a more important cause of SSI than exogenous bacteria. In clean-contaminated, contaminated, and dirty-infected operations, the source and

Table 1 National Research Council Classification of Operative Wounds⁵

Clean (class I)	Nontraumatic No inflammation encountered No break in technique Respiratory, alimentary, or genitourinary tract not entered
Clean-contaminated (class II)	Gastrointestinal or respiratory tract entered without significant spillage Appendectomy Oropharynx entered Vagina entered Genitourinary tract entered in absence of infected urine Biliary tract entered in absence of infected bile Minor break in technique
Contaminated (class III)	Major break in technique Gross spillage from gastrointestinal tract Traumatic wound, fresh Entrance of genitourinary or biliary tracts in presence of infected urine or bile
Dirty and infected (class IV)	Acute bacterial inflammation encountered, without pus Transection of "clean" tissue for the purpose of surgical access to a collection of pus Traumatic wound with retained devitalized tissue, foreign bodies, fecal contamination, delayed treatment, or all of these or from dirty source

Figure 3 The wound infection rate is shown here as a function of bacterial inoculum in three different situations: a dry wound with an adequate concentration of antibiotic (cephalexin > 10 µg/mL), a dry wound with no antibiotic (placebo), and a wet wound with no antibiotic (placebo, wound fluid hematocrit > 8%).¹²

the amount of bacteria are functions of the patient's disease and the specific organs being operated on.

Operations classified as infected are those in which infected tissue and pus are removed or drained, providing a guaranteed inoculum to the surgical site. The inoculum may be as high as 10^{10} bacteria/mL, some of which may already be producing an infection. In addition, some bacteria could be in the growth phase rather than the dormant or lag phase and thus could be more pathogenic. The heavily contaminated wound is best managed by delayed primary closure. This type of management ensures that the wound is not closed over a bacterial inoculum that is almost certain to cause a wound infection, with attendant early and late consequences.

Patients should not have elective surgery in the presence of remote infection, which is associated with an increased incidence of wound infection.⁵ In patients with urinary tract infections, wounds frequently become infected with the same organism. Remote infections should be treated appropriately, and the operation should proceed only under the best conditions possible. If the operation cannot be appropriately delayed, the use of prophylactic and therapeutic antibiotics should be considered [see *Sidebar Antibiotic Prophylaxis of Infection and Tables 2 through 4*].

Preoperative techniques of reducing patient flora, especially endogenous bacteria, are of great concern. Bowel preparation, antimicrobial showers or baths, and preoperative skin decontamination have been proposed frequently. These techniques, particularly preoperative skin decontamination

[see *Sidebar Preoperative Preparation of the Operative Site*], may have specific roles in selected patients during epidemics or in units with high infection rates. As a routine for all patients, however, these techniques are unnecessary, time-consuming, and costly in institutions or units where infection rates are low.

The preoperative shave is a technique in need of reassessment. It is now clear that shaving the evening before an operation is associated with an increased wound infection rate. This increase is secondary to the trauma of the shave and the inevitable small areas of inflammation and infection. If hair removal is required,¹⁵ clipping is preferable and should be done in the OR or the preparation room just before the operative procedure. Shaving, if ever performed, should not be done the night before the operation.

In the past few years, the role of the classic bowel preparation [see *Table 5*] has been questioned [see *Discussion, Infection Prevention in Bowel Surgery, below*].^{16–21} The suggestion has been made that selective gut decontamination (SGD) may be useful in major elective procedures involving the upper gastrointestinal (GI) tract and perhaps in other settings. At present, SGD for prevention of infection cannot be recommended in either the preoperative or the postoperative period.

When infection develops after clean operations, particularly those in which foreign bodies were implanted, endogenous infecting organisms are involved, but the skin is the primary source of the infecting bacteria. The air in the operating room (OR) and other OR sources occasionally become significant in clean cases; the degree of endogenous contamination can be surpassed by that of exogenous contamination. Thus, both the operating team—surgeon, assistants, nurses, and anesthetists—and OR air have been reported as significant sources of bacteria [see *1:8 Preparation of the Operating Room*]. In fact, personnel are the most important source of exogenous bacteria.^{22–24} In the classic 1964 study by the National Academy of Sciences–National Research Council, ultraviolet light (UVL) was efficacious only in the limited situations of clean and ultraclean cases.⁵ There were minimal numbers of endogenous bacteria, and UVL controlled one of the exogenous sources.

Clean air systems have very strong advocates, but they also have equally vociferous critics. It is possible to obtain excellent results in clean cases with implants without using these systems. However, clean air systems are here to stay. Nevertheless, the presence of a clean air system does not mean that basic principles of asepsis and antisepsis should be abandoned, because endogenous bacteria must still be controlled.

The use of impermeable drapes and gowns has received considerable attention. If bacteria can penetrate gown and drapes, they can gain access to the wound. The use of impermeable drapes may therefore be of clinical importance.^{25,26} When wet, drapes of 140-thread-count cotton are permeable to bacteria. It is clear that some operations are wetter than others, but, generally, much can be done to make drapes and gowns impermeable to bacteria. For example, drapes of 270-thread-count cotton that have been waterproofed are impermeable, but they can be washed only 75 times.

Antibiotic Prophylaxis of Infection

Selection

Spectrum. The antibiotic chosen should be active against the most likely pathogens. Single-agent therapy is almost always effective except in colorectal operations, small bowel procedures with stasis, emergency abdominal operations in the presence of polymicrobial flora, and penetrating trauma; in such cases, a combination of antibiotics is usually used because anaerobic coverage is required.

Pharmacokinetics. The half-life of the antibiotic selected must be long enough to maintain adequate tissue levels throughout the operation.

Administration

Dosage, route, and timing. A single preoperative dose that is of the same strength as a full therapeutic dose is adequate in most instances. The single dose should be given IV immediately before skin incision. Administration by the anesthetist is most effective and efficient.

Duration. A second dose is warranted if the duration of the operation exceeds either 3 hours or twice the half-life of the antibiotic. No additional benefit has been demonstrated in continuing prophylaxis beyond the day of the operation, and mounting data suggest that the preoperative dose is sufficient. When massive hemorrhage has occurred (i.e., blood loss equal to or greater than blood volume), a second dose is warranted. Even in emergency or trauma cases, prolonged courses of antibiotics are not justified unless they are therapeutic.^{79,114}

Indications

CLEAN CASES

Prophylactic antibiotics are not indicated in clean operations if the patient has no host risk factors or if the operation does not involve placement of prosthetic materials. Open heart operation and operations involving the aorta of the vessels in the groin require prophylaxis.

Patients in whom host factors suggest the need for prophylaxis include those who have more than three concomitant diagnoses, those whose operations are expected to last longer than 2 hours, and those whose operations are abdominal.⁶ A patient who meets any two of these criteria is highly likely to benefit from prophylaxis. When host factors suggest that the probability of a surgical site infection is significant, administration of cefazolin at induction of anesthesia is appropriate prophylaxis. Vancomycin should be substituted in patients who are allergic to cephalosporins or who are susceptible to major immediate hypersensitivity reactions to penicillin.

When certain prostheses (e.g., heart valves, vascular grafts, and orthopedic hardware) are used, prophylaxis is justified when viewed in the light of the cost of a surgical site infection to the patient's health. Prophylaxis with either cefazolin or vancomycin is appropriate for cardiac, vascular, or orthopedic patients who receive prostheses.

Catheters for dialysis or nutrition, pacemakers, and shunts of various sorts are prone to infection mostly for technical reasons, and prophylaxis is not usually required. Meta-analysis indicates, however, that antimicrobial prophylaxis reduces the infection rate in CSF shunts by 50%.¹¹⁵ Beneficial results may also be achievable for other permanently implanted shunts (e.g., peritoneo-venous) and devices (e.g., long-term venous access catheters and pacemakers); however, the studies needed to confirm this possibility will never be done, because the infection rates are low and the sample sizes would have to be prohibitively large. The placement of such foreign bodies is a clean operation, and the use of antibiotics should be based on local experience. A recent meta-analysis indicates that antibiotic prophylaxis (cefazolin) prevents SSI in breast surgery.¹¹⁶

CLEAN-CONTAMINATED CASES

Abdominal procedures. In biliary tract procedures (open or laparoscopic), prophylaxis is required only for patients at high risk: those whose common bile duct is likely to be explored (because of jaundice, bile duct obstruction, stones in the common bile duct, or a reoperative biliary procedure); those with acute cholecystitis; and those older than 70 years. A single dose of cefazolin is adequate. In hepatobiliary and pancreatic procedures, antibiotic prophylaxis is always warranted because these operations are clean-contaminated, because they are long, and because they are abdominal. Prophylaxis is also warranted for therapeutic endoscopic retrograde cholangiopancreatography. In gastroduodenal procedures, patients whose gastric acidity is normal or high and in whom bleeding, cancer, gastric ulcer, and obstruction are absent are at low risk for infection and require no prophylaxis; all other patients are at high risk and require prophylaxis. Patients undergoing operation for morbid obesity should receive double the usual prophylactic dose¹¹⁷; cefazolin is an effective agent.

Operations on the head and neck (including the esophagus). Patients whose operation is of significance (i.e., involves entry into the oral cavity, the pharynx, or the esophagus) require prophylaxis.

Gynecologic procedures. Patients whose operation is either high-risk cesarean section, abortion, or vaginal or abdominal hysterectomy will benefit from cefazolin. Aqueous penicillin G or doxycycline may be preferable for first-trimester abortions in patients with a history of pelvic inflammatory disease. In patients with cephalosporin allergy, doxycycline is effective for those having hysterectomies and metronidazole for those having cesarean sections. Women delivering by cesarean section should be given the antibiotic immediately after cord clamping.

Urologic procedures. In principle, antibiotics are not required in patients with sterile urine. Patients with positive cultures should be treated. If an operative procedure is performed, a single dose of the appropriate antibiotic will suffice.

(continued)

Economics plays a role in the choice of drape fabric because entirely disposable drapes are expensive. Local institutional factors may be significant in the role of a specific type of drape in the prevention of SSI.

PROBABILITY OF CONTAMINATION

The probability of contamination is largely defined by the nature of the operation [see Table 1]. However, other factors contribute to the probability of contamination; the most obvious is the expected duration of the operative procedure, which, whenever examined, has been significantly correlated with the wound infection rate.^{6,11,13} The longer the procedure lasts, the more bacteria accumulate in a wound; the sources

of bacteria include the patient, the operating team (gowns, gloves with holes, wet drapes), the OR, and the equipment. In addition, the patient undergoing a longer operation is likely to be older, to have other diseases, and to have cancer of—or to be undergoing an operation on—a structure with possible contamination. A longer duration, even of a clean operation, represents increased time at risk for contamination. These points, in addition to pharmacologic considerations, suggest that the surgeon should be alert to the need for a second dose of prophylactic antibiotics [see Sidebar Antibiotic Prophylaxis of Infection].

Abdominal operation is another risk factor not found in the NNIS risk assessment.^{6,8} Significant disease and age are

Antibiotic Prophylaxis of Infection (*continued*)

CONTAMINATED CASES

Abdominal procedures. In colorectal procedures, antibiotics active against both aerobes and anaerobes are recommended. In appendectomy, SSI prophylaxis requires an agent or combination of agents against both aerobes and anaerobes; a single dose of cefoxitin, 2 g IV, or, in patients who are allergic to β -lactam antibiotics, metronidazole, 500 mg IV, is effective. A combination of an aminoglycoside and clindamycin is effective if the appendix is perforated; a therapeutic course of 3 to 5 days is appropriate but does not seem warranted unless the patient is particularly ill. A laparotomy without a precise diagnosis is usually an emergency procedure and demands preoperative prophylaxis. If the preoperative diagnosis is a ruptured viscus (e.g., the colon or the small bowel), both an agent active against aerobes and an agent active against anaerobes are required.

Trauma. The proper duration of antibiotic prophylaxis for trauma patients is a confusing issue—24 hours or less of prophylaxis is probably adequate, and more than 48 hours is certainly unwarranted. When laparotomy is performed for nonpenetrating injuries, prophylaxis should be administered. Coverage of both aerobes and anaerobes is mandatory. The duration of prophylaxis should be less than 24 hours. In cases of penetrating abdominal injury, prophylaxis with either cefoxitin or a combination of agents active against anaerobic and aerobic organisms is required. The duration of prophylaxis should be less than 24 hours, and in many cases, perioperative doses will be adequate. For open fractures, management should proceed as if a therapeutic course were required. For grade I or II injuries, a first-generation cephalosporin will suffice, whereas for grade III injuries, combination therapy is warranted; the duration may vary. For operative repair of fractures, a single dose of cefazolin may be given preoperatively, with a second dose added if the procedure is long. Patients with major soft tissue injury with a danger of spreading infection will benefit from cefazolin, 1 g IV every 8 hours for 1 to 3 days.

DIRTY OR INFECTED CASES

Infected cases require therapeutic courses of antibiotics; prophylaxis is not appropriate in this context. In dirty cases,

particularly those resulting from trauma, contamination and tissue destruction are usually so extensive that the wounds must be left open for delayed primary or secondary closure. Appropriate timing of wound closure is judged at the time of débridement. Antibiotics should be administered as part of resuscitation. Administration of antibiotics for 24 hours is probably adequate if infection is absent at the outset. However, a therapeutic course of antibiotics is warranted if infection is present from the outset or if more than 6 hours elapsed before treatment of the wounds was initiated.

Prophylaxis of Endocarditis

Studies of the incidence of endocarditis associated with dental procedures, endoscopy, or operations that may result in transient bacteremia are lacking. Nevertheless, the consensus is that patients with specific cardiac and vascular conditions are at risk for endocarditis or vascular prosthetic infection when undergoing certain procedures; these patients should receive prophylactic antibiotics.^{118,119} A variety of organisms are dangerous, but viridans streptococci are most common after dental or oral procedures, and enterococci are most common if the portal of entry is the GU or GI tract. Oral amoxicillin now replaces penicillin V or ampicillin because of superior absorption and better serum levels. In penicillin-allergic patients, clindamycin is recommended; alternatives include cephalexin, ceftriaxone, azithromycin, and clarithromycin. When there is a risk of exposure to bowel flora or enterococci, oral amoxicillin may be given. If an IV regimen is indicated, ampicillin may be given, with gentamicin added if the patient is at high risk for endocarditis. In patients allergic to penicillin, vancomycin is appropriate, with gentamicin added in high-risk patients. These parenteral regimens should be reserved for high-risk patients undergoing procedures with a significant probability of bacteremia. [see Tables 3 and 4]

The new recommendations of the American Heart Association have reduced the cardiac conditions needing prophylaxis and the procedures that warrant antibiotics.^{118,119} There should be a reduction in antibiotic use as a result.

additional factors that play a role in outcome; however, because the major concentrations of endogenous bacteria are located in the abdomen, abdominal operations are more likely to involve bacterial contamination.

For some years, postoperative contamination of the wound has been considered unlikely. However, one report of SSI in sternal incisions cleaned and redressed 4 hours postoperatively clearly shows that wounds can be contami-

Table 2 Parenteral Antibiotics Recommended for Prophylaxis of Surgical Site Infection

	Antibiotic	Dose	Route of Administration
For coverage against aerobic gram-positive and gram-negative organisms	Cefazolin	1 g	IV or IM (IV preferred)
If patient is allergic to cephalosporins or if methicillin-resistant organisms are present	Vancomycin	1 g	IV
Combination regimens for coverage against gram-negative aerobes and anaerobes	Cefoxitin	1–2 g	IV
	or Cefazolin	1–2 g	IV
	plus Metronidazole	0.5 g	IV
	or Ampicillin/sulbactam	3 g	IV
Allergic to penicillin or cephalosporins	Clindamycin plus Gentamicin, ciprofloxacin, aztreonam	600 mg	IV
For single-agent coverage against gram-negative aerobes and anaerobes	Cefoxitin	1–2 g	IV

Table 3 Conditions and Procedures that Require Antibiotic Prophylaxis against Endocarditis^{118,119}

Conditions that Warrant Prophylaxis

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
Previous infective endocarditis
Congenital heart disease (CHD)
Unrepaired cyanotic CHD, including palliative shunts and conduits
Complete repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
Cardiac transplantation recipients who develop cardiac valvulopathy

Procedures that Warrant Prophylaxis

Dental or oropharyngeal procedures that
1. manipulate gingival tissue or the periapical region of the teeth
2. perforate the oral mucosa
Incision and drainage, manipulation, or débridement of infected sites regardless of location
Gastrointestinal (GI) or genitourinary (GU) procedures for which antibiotics to prevent surgical site infection would be administered
Endoscopy of GI tract or uninfected GU tract prophylaxis is NO longer recommended

nated and become infected in the postoperative period.²⁷ Accordingly, use of a dry dressing for 24 hours seems prudent.

BACTERIAL PROPERTIES

Not only is the size of the bacterial inoculum important; the bacterial properties of virulence and pathogenicity are also significant. The

most obvious pathogenic bacteria in surgical patients are gram-positive cocci (e.g., *Staphylococcus aureus* and streptococci). With modern hygienic practice, it would be expected that *S. aureus* would be found mostly in clean cases, with a wound infection incidence of 1 to 2%; however, it is, in fact, an increasingly common pathogen in SSIs. Surveillance can be very useful in identifying either wards or surgeons with increased rates. Operative procedures in infected areas have an increased infection rate because of the high inoculum with actively pathogenic bacteria.

Table 4 Antibiotics for Prevention of Endocarditis^{118,119}

Manipulative Procedure	Prophylactic Regimen*	
	Usual	In Patients with Penicillin Allergy
Dental procedures likely to cause gingival bleeding; operations or instrumentation of the upper respiratory tract	Oral Amoxicillin 2 g 1 hr before procedure	Oral Clindamycin, [†] 600 mg 1 hr before procedure or Cephalexin, [†] 1 g 1 hr before procedure or Azithromycin or clarithromycin, 500 mg 1 hr before procedure
	Parenteral Ampicillin, 2 g IM or IV 30 min before procedure or Cefazolin or ceftriaxone 1 g IM or IV	Parenteral Clindamycin, 600 mg IV within 30 min before procedure or Cefazolin or ceftriaxone, 1 g IM or IV within 30 min before procedure
Infected gastrointestinal or genitourinary operation; abscess drainage	Oral Amoxicillin, 2 g 1 hr before procedure Parenteral Ampicillin, 2 g IM or IV within 30 min before procedure; if risk of endocarditis is considered high, add gentamicin, 1.5 mg/kg (to maximum of 120 mg) IM or IV 30 min before procedure	Parenteral Vancomycin, 1 g IV infused slowly over 1 hr, beginning 1 hr before procedure; if risk of endocarditis is considered high, add gentamicin, 1.5 mg/kg (to maximum of 120 mg) IM or IV 30 min before procedure [‡]

*Pediatric dosages are as follows: oral amoxicillin, 50 mg/kg; oral or parenteral clindamycin, 20 mg/kg; oral cephalexin or cefadroxil, 50 mg/kg; oral azithromycin or clarithromycin, 15 mg/kg; parenteral ampicillin, 50 mg/kg; parenteral cefazolin, 25 mg/kg; parenteral gentamicin, 2 mg/kg. The total pediatric dose should not exceed the total adult dose.

[†]Patients with a history of immediate-type sensitivity to penicillin should not receive these agents.

[‡]High-risk patients should also receive ampicillin, 1 g IM or IV, or amoxicillin, 1 g PO, 6 hours after the procedure.

Preoperative Preparation of the Operative Site

The sole reason for preparing the patient's skin before an operation is to reduce the risk of wound infection. A preoperative antiseptic bath is not necessary for most surgical patients, but their personal hygiene must be assessed and preoperative cleanliness established. Multiple preoperative baths may prevent postoperative infection in selected patient groups, such as those who carry *Staphylococcus aureus* on their skin or who have infectious lesions. Chlorhexidine gluconate is the recommended agent for such baths.¹²⁰

Hair should not be removed from the operative site unless it physically interferes with accurate anatomic approximation of the wound edges.¹⁵ If hair must be removed, it should be clipped in the OR.¹⁵ Shaving hair from the operative site, particularly on the evening before operation or immediately before wound incision in the OR, increases the risk of wound infection. Depilatories are not recommended, because they cause serious irritation and rashes in a significant number of patients, especially when used near the eyes and the genitalia.¹²¹

In emergency procedures, obvious dirt, grime, and dried blood should be mechanically cleansed from the operative site by using sufficient friction. In one study, cleansing of contaminated wounds by means of ultrasound débridement was compared with high-pressure irrigation and soaking. Both ultrasound débridement and high-pressure irrigation were also effective in reducing the wound infection rate in experimental wounds contaminated with a subinfective dose of *S. aureus* and colloidal clay.¹²²

For nonemergency procedures, the necessary reduction in microorganisms can be achieved by using povidoneiodine (10% available povidoneiodine and 1% available iodine) or chlorhexidine gluconate both for mechanical cleansing of the intertriginous folds and the umbilicus and for painting the operative site. Which skin antiseptic is optimal is unclear. The best option appears to be chlorhexidine gluconate or an iodophor.¹²³ The patient should be assessed for evidence of sensitivity to the antiseptic (particularly if the agent contains iodine) to minimize the risk of an allergic reaction. What some patients report as iodine allergies are actually burns. Iodine in alcohol or in water is associated with an increased risk of skin irritation,⁹⁶ particularly at the edges of the operative field, where the iodine concentrates as the alcohol evaporates. Iodine should therefore be removed after sufficient contact time with the skin, especially at the edges. Iodophors do not irritate the skin and thus need not be removed.

The preoperative hospital stay has frequently been found to make an important contribution to wound infection rates.¹³ The usual explanation is that during this stay, either more endogenous bacteria are present or commensal flora is replaced by hospital flora. More likely, the patient's clinical picture is a complex one, often entailing exhaustive workup of more than one organ system, various complications, and a degree of illness that radically changes the host's ability to

deal with an inoculum, however small. Therefore, multiple factors combine to transform the hospitalized preoperative patient into a susceptible host. Same-day admission should eliminate any bacterial impact associated with the preoperative hospital stay.

Bacteria with multiple antibiotic resistance (e.g., methicillin-resistant *S. aureus* [MRSA], *Staphylococcus epidermidis*, and vancomycin-resistant enterococci [VRE]) can be associated with significant SSI problems. In particular, staphylococci, with their natural virulence, present an important hazard if inappropriate prophylaxis is used.

Many surgeons consider it inappropriate or unnecessary to obtain good culture and sensitivity data on SSIs; instead of conducting sensitivity testing, they simply drain infected wounds, believing that the wounds will heal. However, there have been a number of reports of SSIs caused by unusual organisms^{24,27,28}; these findings underscore the usefulness of culturing pus or fluid when an infection is being drained. SSIs caused by antibiotic-resistant organisms or unusual pathogens call for specific prophylaxis, perhaps other infection control efforts, and, if the problem persists, a search for a possible carrier or a common source.^{22-24,27,28}

SURGEONS AND BACTERIA

The surgeon's perioperative rituals are designed to reduce or eliminate bacteria from the operative field. Many old habits are obsolete [see 1:8 *Preparation of the Operating Room and Discussion, Hand Washing, below*].

Nonetheless, it is clear that surgeons can influence SSI rates.¹⁴ The refusal to use delayed primary closure or secondary closure is an example. Careful attention to the concepts of asepsis and antisepsis in the preparation and conduct of the operation is important. Although no single step in the ritual of preparing a patient for the operative procedure is indispensable, it is likely that certain critical standards of behavior must be maintained to achieve good results.

The measurement and publication of data about individuals or hospitals with high SSI rates have been associated with a diminution of those rates [see Table 6].^{13,14,29} It is uncertain by what process the diffusion of these data relates to the observed improvements. Although surveillance has unpleasant connotations, it provides objective data that individual surgeons are often too busy to acquire but that can contribute to improved patient care. For example, such data can be useful in identifying problems (e.g., the presence of MRSA, a high SSI incidence, or clusters), maintaining quality assurance, and allowing comparison with accepted standards.

Environment: Local Factors

Local factors influence SSI development because they affect the size of the bacterial inoculum that is required

Table 5 Effect of Surveillance and Feedback on Wound Infection Rates in Two Hospitals²⁹

		Period 1	Period 2*
Hospital A	Number of wounds	1,500	1,447
	Wound infection rate	8.4%	3.7%
Hospital B	Number of wounds	1,746	1,939
	Wound infection rate	5.7%	3.7%

*Periods 1 and 2 were separated by an interval during which feedback on wound infection rates was analyzed.

Table 6 Determinants of Infection and Factors that Influence Wound Infection Rates²⁹

Variable	Determinant of Infection		
	Bacteria	Wound Environment (Local Factors)	Host Defense Mechanisms (Systemic Factors)
Bacterial numbers in wound	a		
Potential contamination	a		
Preoperative shave	a		
Presence of three or more diagnoses			c
Age		b	c
Duration of operation	a	b	c
Abdominal operation Relative value unit > 10 Emergency surgery	a	b	c
ASA class III, IV, or V			c
O ₂ tension		b	
Glucose control			c

Age ≥ 40 ¹⁰			c
Radiotherapy ¹⁰			c
> 2 alcoholic drinks ¹⁰			c

ASA = American Society of Anesthesiologists.

to produce an infection: in a susceptible wound, a smaller inoculum produces infection [see Figure 2].

THE SURGEON'S INFLUENCE

Most of the local factors that make a surgical site favorable to bacteria are under the control of the surgeon. Although Halsted usually receives, deservedly so, the credit for having established the importance of technical excellence in the OR in preventing infection, individual surgeons in the distant past achieved remarkable results by careful attention to cleanliness and technique.³⁰ The halstedian principles dealt with hemostasis, sharp dissection, fine sutures, anatomic dissection, and the gentle handling of tissues. Mass ligatures, large or braided nonabsorbable sutures, necrotic tissue, and the creation of hematomas or seromas must be avoided, and foreign materials must be judiciously used because these techniques and materials change the size of the inoculum required to initiate an infectious process. Logarithmically fewer bacteria are required to produce infection in the presence of a foreign body (e.g., suture, graft, metal, or pacemaker) or necrotic tissue (e.g., that caused by gross hemostasis or injudicious use of electrocautery devices).

The differences in inoculum required to produce wound infections can be seen in a model in which the two variables

are the wound hematocrit and the presence of an antibiotic [see Figure 3]. In the absence of an antibiotic and in the presence of wound fluid with a hematocrit of more than 8%, 10 bacteria yield a wound infection rate of 20%. In a technically good wound with no antibiotic, however, 1,000 bacteria produce a wound infection rate of 20%.¹² In the presence of an antibiotic, 10⁵ to 10⁶ bacteria are required.

Drains

The use of drains varies widely and is very subjective. All surgeons are certain that they understand when to use a drain. However, certain points are worth noting. It is now recognized that a simple Penrose drain may function as a drainage route but is also an access route by which pathogens can reach the patient.³¹ It is important that the operative site not be drained through the wound. The use of a closed suction drain reduces the potential for contamination and infection.

Many operations on the gastrointestinal (GI) tract can be performed safely without employing prophylactic drainage.³² A review and meta-analysis from 2004 concluded that (1) after hepatic, colonic, or rectal resection with primary anastomosis and after appendectomy for any stage of appendicitis, drains should be omitted (recommendation grade A),

and (2) after esophageal resection and total gastrectomy, drains should be used (recommendation grade D). Additional randomized, controlled trials will be required to determine the value of prophylactic drainage for other GI procedures, especially those involving the upper GI tract.

Duration of Operation

In most studies, contamination certainly increases with time (see above).^{6,11,13} Wound edges can dry out, become macerated, or in other ways be made more susceptible to infection (i.e., requiring fewer bacteria for development of infection). Speed and poor technique are not suitable approaches; expeditious operation is appropriate.

Electrocautery

The use of electrocautery devices (but not the harmonic scalpel) has been clearly associated with an increase in the incidence of superficial SSIs. However, when such devices are properly used to provide pinpoint coagulation (for which the bleeding vessels are best held by fine forceps) or to divide tissues under tension, there is minimal tissue destruction, no charring, and no change in the wound infection rate.³¹

PATIENT FACTORS

Local Blood Flow

Local perfusion can greatly influence the development of infection, as is seen most easily in the tendency of the patient with peripheral vascular disease to acquire infection of an extremity. As a local problem, inadequate perfusion reduces the number of bacteria required for infection, in part because inadequate perfusion leads to decreased tissue levels of oxygen. Shock, by reducing local perfusion, also greatly enhances susceptibility to infection. Fewer organisms are required to produce infection during or immediately after shock [see Figure 4].

To counter these effects, the arterial oxygen tension (P_{aO_2}) must be translated into an adequate subcutaneous oxygen level (determined by measuring transcutaneous oxygen tension)³³; this, together with adequate perfusion, will provide local protection by increasing the number of bacteria required to produce infection. Provision of supplemental oxygen in the perioperative period may lead to a reduced SSI rate, probably as a consequence of increased tissue oxygen tension,³⁴ although the value of this practice has been questioned.³⁵ If the patient is not intubated, a mask, not nasal prongs, is required.³⁶

Barrier Function

Inadequate perfusion may also affect the function of other organs, and the resulting dysfunction will, in turn, influence the patient's susceptibility to infection. For example, ischemia-reperfusion injury to the intestinal tract is a frequent consequence of hypovolemic shock and bloodstream infection. Inadequate perfusion of the GI tract may also occur during states of fluid and electrolyte imbalance or when cardiac output is marginal. In experimental studies, altered blood flow has been found to be associated with the breakdown of bowel barrier function—that is, the inability of the

intestinal tract to prevent bacteria, their toxins, or both from moving from the gut lumen into tissue at a rate too fast to permit clearance by the usual protective mechanisms. A variety of experimental approaches aimed at enhancing bowel barrier function have been studied; at present, however, the most clinically applicable method of bowel protection is initiation of enteral feeding (even if the quantity of nutrients provided does not satisfy all the nutrient requirements) and administration of the amino acid glutamine [see 8:22 *Nutritional Support*]. Glutamine is a specific fuel for enterocytes and colonocytes and has been found to aid recovery of damaged intestinal mucosa and enhance barrier function when administered either enterally or parenterally.

Advanced Age

Aging is associated with structural and functional changes that render the skin and subcutaneous tissues more susceptible to infection. These changes are immutable; however, they must be evaluated in advance and addressed by excellent surgical technique and, on occasion, prophylactic antibiotics [see *Sidebar Antibiotic Prophylaxis of Infection*]. SSI rates increase with aging until the age of 65 years, after which point, the incidence appears to decline.³⁷

Host Defense Mechanisms

The systemic response is designed to control and eradicate infection. Many factors can inhibit systemic host defense mechanisms; some are related to the surgical disease and others to the patient's underlying disease or diseases and the events surrounding the operation.

SURGEON-RELATED FACTORS

There are a limited number of ways in which the surgeon can improve a patient's systemic responses to surgery. Nevertheless, when appropriate, attempts should be made to modify the host. The surgeon and the operation are both capable of reducing immunologic efficacy; hence, the operative procedure should be carried out in as judicious a manner as possible. Minimal blood loss, avoidance of shock, and maintenance of blood volume, tissue perfusion, and tissue oxygenation will minimize trauma and will reduce the secondary, unintended immunologic effects of major procedures.

Diabetes has long been recognized as a risk factor for infection and for SSI in particular. Three studies from the past decade demonstrated the importance of glucose control for reducing SSI rates in both diabetic and nondiabetic patients who underwent operation,^{38,39} as well as in critically ill intensive care unit patients.⁴⁰ Glucose control is required throughout the entire perioperative period. The beneficial effect appears to lie in the enhancement of host defenses. The surgical team must also ensure maintenance of adequate tissue oxygen tension^{33,34} and maintenance of normothermia.⁴¹

When abnormalities in host defenses are secondary to surgical disease, the timing of the operation is crucial to outcome. With acute and subacute inflammatory processes, early

Figure 4 Animals exposed to hemorrhagic shock followed by resuscitation show an early decreased resistance to wound infection. There is also a persistent influence of shock on the development of wound infection at different times of inoculation after shock. The importance of inoculum size (10^6 /mL to 10^8 /mL) and the effect of antibiotic on infection rates are evident at all times of inoculation.¹⁰⁹

operation helps restore normal immune function. Deferral of definitive therapy frequently compounds problems.

PATIENT FACTORS

Surgeons have always known that the patient is a significant variable in the outcome of operation. Various clinical states are associated with altered resistance to infection. In all patients, but particularly those at high risk, SSI creates not only wound complications but also significant morbidity (e.g., reoperation, incisional hernia, secondary infection, impaired mobility, increased hospitalization, delayed rehabilitation, or permanent disability) and occasional mortality.²³ SENIC has proposed that the risk of wound infection be assessed not only in terms of probability of contamination but also in relation to host factors.^{6,7,9} According to this study, patients most clearly at risk for wound infection are those with three or more concomitant diagnoses; other patients who are clearly at risk are those undergoing a clean-contaminated or contaminated abdominal procedure and those undergoing any procedure expected to last longer than 2 hours. These last two risk groups are affected by a bacterial component, but all those patients who are undergoing major abdominal procedures or lengthy operations generally have a significant primary pathologic condition and are usually older, with an increased frequency of concomitant conditions. The NNIS system uses most of the same concepts but expresses them differently. In the NNIS study, host factors in the large study are evaluated in terms of the ASA score. The duration of the operation is measured differently as well, with a lengthy

operation being defined by the NNIS as one that is at or above the 75th percentile for operating time. Bacterial contamination remains a risk factor, but the operative site is eliminated.⁸

Shock has an influence on the incidence of wound infection [see Figure 4]. This influence is most obvious in cases of trauma, but there are significant implications for all patients in regard to maintenance of blood volume, hemostasis, and oxygen-carrying capacity. The effect of shock on the risk of infection appears to be not only immediate (i.e., its effect on local perfusion) but also late because systemic responses are blunted as local factors return to normal.

Advanced age, transfusion, and the use of steroids and other immunosuppressive drugs, including chemotherapeutic agents, are associated with an increased risk of SSI.^{42,43} Often, these factors cannot be altered; however, the proper choice of operation, the appropriate use of prophylaxis, and meticulous surgical technique can reduce the risk of such infection by maintaining patient homeostasis, reducing the size of any infecting microbial inoculum, and creating a wound that is likely to heal primarily.

Smoking is associated with a striking increase in SSI incidence. As little as 1 week of abstinence from smoking will make a positive difference.⁴⁴

Pharmacologic therapy can affect host response as well. Nonsteroidal anti-inflammatory drugs that attenuate the production of certain eicosanoids can greatly alter the adverse effects of infection by modifying fever and cardiovascular effects. Operative procedures involving inhalational anesthetics result in an immediate rise in plasma cortisol concentrations. The steroid response and the associated immunomodulation can be modified by using high epidural anesthesia as the method of choice; pituitary adrenal

activation will be greatly attenuated. Some drugs that inhibit steroid elaboration (e.g., etomidate) have also been shown to be capable of modifying perioperative immune responses. Using this vast database of NSQIP, Neumayer and colleagues integrated most of these variables into an expanded risk assessment [see Table 6].¹⁰

ANESTHESIOLOGIST-RELATED FACTORS

A 2000 commentary in *The Lancet* by Donal Buggy considered the question of whether anesthetic management could influence surgical wound healing.⁴⁵ In addition to the surgeon- and patient-related factors already discussed (see above), Buggy cogently identified a number of anesthesiologist-related factors that could contribute to better wound healing and reduced wound infection. Some of these factors (e.g., pain control, epidural anesthesia, and autologous transfusion) are unproven but nonetheless make sense and should certainly be tested. Others (e.g., tissue perfusion, intravascular volume, and—significantly—maintenance of normal perioperative body temperature) have undergone formal evaluation. Very good studies have shown that dramatic reductions in SSI rates can be achieved through careful avoidance of hypothermia.^{41,46} Patient-controlled analgesia pumps are known to be associated with increased SSI rates, through a mechanism that is currently unknown.⁴⁷ Infection control practices are required of all practitioners; contamination of anesthetic drugs by bacteria has resulted in numerous small outbreaks of SSI.^{48,49}

As modern surgical practice has evolved and the variable of bacterial contamination has come to be generally well managed, the importance of all members of the surgical team in the prevention of SSI has become increasingly apparent. The crux of Buggy's commentary may be expressed as follows: details make a difference, and all of the participants in a patient's surgical journey can contribute to a continuing decrease in SSI. It is a systems issue.

INTEGRATION OF DETERMINANTS

As operative infection rates slowly fall, despite the performance of increasingly complex operations in patients at greater risk, surgeons are approaching the control of infection with a broader view than simply that of asepsis and antisepsis. This new, broader view must take into account many variables, of which some have no relation to bacteria, but all play a role in SSI [see Table 6 and Figure 1].

To estimate risk, one must integrate the various determinants of infection in such a way that they can be applied to patient care. Much of this exercise is vague. In reality, the day-to-day practice of surgery includes a risk assessment that is essentially a form of logistic regression, although not recognized as such. Each surgeon's assessment of the probability of whether an SSI will occur takes into account the determining variables:

$$\begin{aligned} \text{Probability of SSI} = & \\ & x + a \text{ (bacteria)} + b \text{ (environment: local factors)} \\ & + c \text{ (host defense mechanisms: systemic factors)} \end{aligned}$$

Discussion

ANTIBIOTIC PROPHYLAXIS OF SSI

It is difficult to understand why antibiotics have not always prevented SSI successfully. Certainly, surgeons were quick to appreciate the possibilities of antibiotics; nevertheless, the efficacy of antibiotic prophylaxis was not proved until the late 1960s.¹² Studies before then had major design flaws—principally, the administration of the antibiotic some time after the start of the operation, often in the recovery room. The failure of studies to demonstrate efficacy and the occasional finding that prophylactic antibiotics worsened rather than improved outcome led in the late 1950s to profound skepticism about prophylactic antibiotic use in any operation.

The principal reason for the apparent inefficacy was inadequate understanding of the biology of SSIs. Fruitful study of antibiotics and how they should be used began after physiologic groundwork established the importance of local blood flow, maintenance of local immune defenses, adjuvants, and local and systemic perfusion.⁵⁰

The key antibiotic study, which was conducted in guinea pigs, unequivocally proved the following about antibiotics⁵¹:

1. They are most effective when given before inoculation of bacteria.
2. They are ineffective if given 3 hours after inoculation.
3. They are of intermediate effectiveness when given between these times [see Figure 5].

Although efficacy with a complicated regimen was demonstrated in 1964,⁵² the correct approach was not defined until 1969.¹² Established by these studies are the philosophical and practical bases of the principles of antibiotic prophylaxis of

Figure 5 In a pioneer study of antibiotic prophylaxis,⁵¹ the diameter of lesions induced by staphylococcal inoculation 24 hours earlier was observed to be critically affected by the timing of penicillin administration with respect to bacterial inoculation.

SSI in all surgical arenas^{12,51}: that prophylactic antibiotics must be given preoperatively within 2 hours of the incision, in full dosage, parenterally, and for a very limited period. These principles remain essentially unchanged despite minor modifications from innumerable subsequent studies.^{53–57} Prophylaxis for colorectal operations is discussed elsewhere [see Infection Prevention in Bowel Surgery, *below*].

Principles of Patient Selection

Patients must be selected for prophylaxis on the basis of either their risk for SSI or the cost to their health if an SSI develops (e.g., after implantation of a cardiac valve or another prosthesis). The most important criterion is the degree of bacterial contamination expected to occur during the operation. The traditional classification of such contamination was defined in 1964 by the historic National Academy of Sciences–National Research Council study.⁵ The important features of the classification are its simplicity, ease of understanding, ease of coding, and reliability. Classification is dependent on only one variable—the bacterial inoculum—and the effects of this variable are now controllable by antimicrobial prophylaxis. Advances in operative technique, general care, antibiotic use, anesthesia, and surveillance have reduced SSI rates in all categories that were established by this classification.^{6,13,14,51}

In 1960, after years of negative studies, it was said, “Nearly all surgeons now agree that the routine use of prophylaxis in clean operations is unnecessary and undesirable.”⁵⁸ Since then, much has changed: there are now many clean operations for which no competent surgeon would omit the use of prophylactic antibiotics, particularly as procedures become increasingly complex and prosthetic materials are used in patients who are older, sicker, or immunocompromised.

A separate risk assessment that integrates host and bacterial variables (i.e., whether the operation is dirty or contaminated, is longer than 2 hours, or is an abdominal procedure and whether the patient has three or more concomitant diagnoses) segregates more effectively those patients who are prone to an increased incidence of SSI [see Integration of Determinants of Infection, *below*]. This approach enables the surgeon to identify those patients who are likely to require preventive measures, particularly in clean cases, in which antibiotics would normally not be used.⁶

The prototypical clean operation is an inguinal hernia repair. Technical approaches have changed dramatically over the past 10 years, and most primary and recurrent hernias are now treated with a tension-free mesh-based repair. The use of antibiotics has become controversial. In the era of repairs under tension, there was some evidence to suggest that a perioperative antibiotic (in a single preoperative dose) was beneficial.⁵⁹ Current studies, however, do not support antibiotic use in tension-free mesh-based inguinal hernia repairs.^{60,61} On the other hand, if surveillance indicates that there is a local or regional problem⁶² with SSI after hernia surgery, antibiotic prophylaxis (again in the form of a single preoperative dose) is appropriate. Without significantly more supportive data, prophylaxis for clean cases cannot be recommended unless specific risk factors are present.

Data suggest that prophylactic use of antibiotics may contribute to secondary *Clostridium difficile* disease; accordingly, caution should be exercised when widening the indications

for prophylaxis is under consideration.⁶³ If local results are poor, surgical practice should be reassessed before antibiotics are prescribed.

Antibiotic Selection and Administration

When antibiotics are given more than 2 hours before operation, the risk of infection is increased.^{53,55} IV administration in the OR or the preanesthetic room guarantees appropriate levels at the time of incision. The organisms likely to be present dictate the choice of antibiotic for prophylaxis. The cephalosporins are ideally suited to prophylaxis: their features include a broad spectrum of activity, an excellent ratio of therapeutic to toxic dosages, a low rate of allergic responses, ease of administration, and attractive cost advantages. Mild allergic reactions to penicillin are not contraindications for the use of a cephalosporin.

Physicians like new drugs and often tend to prescribe newer, more expensive antibiotics for simple tasks. First-generation cephalosporins (e.g., cefazolin) are ideal agents for prophylaxis. Third-generation cephalosporins are not: they cost more, are not more effective, and promote emergence of resistant strains.^{64,65}

The most important first-generation cephalosporin for surgical patients continues to be cefazolin. Administered IV in the OR at the time of skin incision, it provides adequate tissue levels throughout most of the operation. A second dose administered in the OR after 3 hours will be beneficial if the procedure lasts longer than that. Data on all operative site infections are imprecise, but SSIs can clearly be reduced by this regimen. No data suggest that further doses are required for prophylaxis.

Fortunately, cefazolin is effective against both gram-positive and gram-negative bacteria of importance, unless significant anaerobic organisms are encountered. The significance of anaerobic flora has been disputed, but for elective colorectal surgery,⁶⁶ abdominal trauma,^{67,68} appendicitis,⁶⁹ or other circumstances in which penicillin-resistant anaerobic bacteria are likely to be encountered, coverage against both aerobic and anaerobic gram-negative organisms is strongly recommended and supported by the data.

Despite several decades of studies, prophylaxis is not always properly implemented.^{53,55,69,70} Unfortunately, didactic education is not always the best way to change behavior. Preprinted order forms⁷¹ and a reminder sticker from the pharmacy⁷² have proved to be effective methods of ensuring correct use.

The commonly heard decision “This case was tough; let’s give an antibiotic for 3 to 5 days” has no data to support it and should be abandoned. The extended duration is associated with an increase in MRSA SSIs.⁷³ Differentiation between prophylaxis and therapy is important. A therapeutic course for perforated diverticulitis or other types of peritoneal infection is appropriate. Data on casual contamination associated with trauma or with operative procedures suggest that 24 hours of prophylaxis or less is quite adequate.^{74–76} Mounting evidence suggests that a single preoperative dose is good care and that additional doses are not required.

Trauma Patients

The efficacy of antibiotic administration on arrival in the emergency department as an integral part of resuscitation has

been clearly demonstrated.⁷⁷ The most common regimens have been (1) a combination of an aminoglycoside and clindamycin and (2) cefoxitin alone. These two regimens or variations thereof have been compared in a number of studies.^{41,68,76,77} They appear to be equally effective, and either regimen can be recommended with confidence. For prophylaxis, there appears to be a trend toward using a single drug: cefoxitin or cefotetan.⁵⁶ If therapy is required because of either a delay in surgery, terrible injury, or prolonged shock, the combination of an agent that is effective against anaerobes with an aminoglycoside seems to be favored. Because aminoglycosides are nephrotoxic, they must be used with care in the presence of shock.

In many of the trauma studies just cited, antibiotic prophylaxis lasted for 48 hours or longer. Subsequent studies, however, indicated that prophylaxis lasting less than 24 hours is appropriate.^{75,76,78} Single-dose prophylaxis is appropriate for patients with closed fractures.⁷⁹

Complications

Complications of antibiotic prophylaxis are few. Although data linking prophylaxis to the development of resistant organisms are meager, resistant microbes have developed in every other situation in which antibiotics have been used, and it is reasonable to expect that prophylaxis in any ecosystem will have the same result, particularly if selection of patients is poor, if prophylaxis lasts too long, or if too many late-generation agents are used.

A rare but important complication of antibiotic use is pseudomembranous enterocolitis, which is induced most commonly by clindamycin, the cephalosporins, and ampicillin [see 8:16 *Nosocomial Infection*].⁶³ The common denominator among different cases of pseudomembranous enterocolitis is hard to identify. Diarrhea and fever can develop after administration of single doses of prophylactic antibiotics. The condition is rare, but difficulties occur because of failure to make a rapid diagnosis.

Current Issues

The most significant questions concerning prophylaxis of SSIs already have been answered.

The problem has been the implementation of the strategies known to work. Table 7 outlines seven measures known with hard data to be important in the reduction of SSI. These management approaches are integrated into the Surgical Care Improvement Project⁸⁰ and the Surgical Infection Prevention Project.⁸¹ Single hospitals have used these criteria in ongoing quality improvement programs.⁸² More impressive is the collaborative reported by Dellinger and colleagues in which 56 hospitals tracked, monitored, and internally fed back the seven variables in Table 7 and demonstrated that as compliance increased, SSI rates came down.⁸³ An important remaining issue is the proper duration of prophylaxis in complicated cases, in the setting of trauma, and in the presence of foreign bodies. No change in the criteria for antibiotic prophylaxis is required in laparoscopic procedures; the risk of infection is lower in such cases.^{84,85} Cost factors are important and may justify the endless succession of studies that compare new drugs in competition for appropriate clinical niches.

Further advances in patient selection may take place but will require analysis of data from large numbers of patients

Table 7 Quality Improvement Objectives to Reduce Surgical Site Infections^{80,83}

Timeliness of antibiotics

and a distinction between approaches to infection of the wound, which is only part of the operative field, and approaches to infections directly related to the operative site. These developments will define more clearly the prophylaxis requirements of patients whose operations are clean but whose risk of wound or operative site infection is increased.

A current issue of some concern is loss of infection surveillance capability. Infection control units have been shown to offer a number of benefits in the institutional setting, such as the following:

1. Identifying epidemics caused by common or uncommon organisms^{24,27,57}
2. Establishing correct use of prophylaxis (timing, dose, duration, and choice)^{53,56,74}
3. Documenting costs, risk factors, and readmission rates^{86,87}
4. Monitoring postdischarge infections and secondary consequences of infections⁸⁸⁻⁹⁰
5. Ensuring patient safety⁹¹
6. Managing MRSA and VRE⁹²

S. aureus—in particular, MRSA—is a major cause of SSI.⁹² Cross-infection problems are a concern, in a manner reminiscent of the preantibiotic era. Hand washing (see below) is coming back into fashion, consistent with the professional behavior toward cross-infection characteristic of the preantibiotic era. At present, hard evidence is lacking, but clinical observation suggests that *S. aureus* SSIs are especially troublesome and destructive of local tissue and require a longer time to heal than other SSIs do. When *S. aureus* SSIs occur after cardiac surgery, thoracotomy, or joint replacement, their consequences are significant. Prevention in these settings is important. When nasal carriage of *S. aureus* has been identified, mupirocin may be administered intranasally to reduce the incidence of *S. aureus* SSIs.⁹³

The benefits of infection surveillance notwithstanding, as the business of hospital care has become more expensive and financial control more rigid, the infection control unit is a hospital component that many administrators have come to consider a luxury and therefore expendable. Consequently, surveillance as a quality control and patient safety mechanism has been diminished.

It is apparent that SSIs have huge clinical and financial implications [see *Sidebar Patient Safety and Antibiotic Use*]. Patients with infections tend to be sicker and to undergo more complex operations. Therefore, higher infection rates translate into higher morbidity and mortality as well as higher cost to the hospital, the patient, and society as a whole. With increasingly early discharge becoming the norm, delayed diagnosis of postdischarge SSI and the complications thereof

Patient Safety and Antibiotic Use

Prophylactic antibiotics have been considered to be a harmless manner in which to prevent surgical site infections. The evidence is that a single dose of prophylactic antibiotics can precipitate *Clostridium difficile* pseudomembranous enterocolitis.⁶³ These can be as malignant as the same entity caused by therapeutic antibiotic regimens.

Although the principles of delivery of added prophylactic antibiotics and their duration have been established for a long time, the evidence is clear that adherence to these principles is frequently poor. Two areas that are primarily at fault are the timing of administration of the first dose and whether it gets given and the duration of use of prophylactic antibiotics.^{43,70-72} The principles are (1) that the drug must be at the site of the wound at the time of incision and (2) a duration longer than 24 hours has no positive impact on SSI and may have a negative one. The inability of hospitals around the world to ensure the short postoperative duration of prophylaxis is a puzzle but is clear in all studies thus far performed.

Although prophylactic antibiotics are not the only stimulus to produce resistant microflora, their control and correct management will contribute to decreasing the incidence of methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococcus (VRE). MRSA, in particular, is now found in community practice clearly as a result of excessive antibiotic use. The key to effective prophylactic antibiotics use and decreased pressure for antibiotic resistance can be simplified to the right drug, the right timing, and the right duration. The increased use of third- and fourth-generation antibiotics is to be strongly discouraged.

The new recommendations for the use of antibiotics in the prevention of infective endocarditis in association with either dental or other operative procedures are clear. The number of conditions has been reduced and clarified, and the recommendations regarding procedures have been greatly simplified.^{118,119}

All recommendations for prophylactic antibiotics, whatever the indication, suggest the use of first- or second-generation cephalosporins, ampicillin or its derivatives, metronidazole, and first-generation erythromycins and aminoglycosides.^{56,118}

is a growing problem.⁸⁸⁻⁹⁰ Effective use of institutional databases may contribute greatly to identification of this problem.⁸⁹

Clearly, the development of effective mechanisms for identifying and controlling SSIs is in the interests of all associated with the delivery of health care.⁹¹ The identification of problems by means of surveillance and feedback can make a substantial contribution to reducing SSI rates [see Table 6].^{13,91}

HAND WASHING

The purpose of cleansing the surgeon's hands is to reduce the numbers of resident flora and transient contaminants, thereby decreasing the risk of transmitting infection. Although the proper duration of the hand scrub is still subject to debate, evidence suggests that a 120-second scrub is sufficient, provided that a brush is used to remove the bacteria residing in the skin folds around the nails.⁹⁴ The nail folds, the nails, and the fingertips should receive the most attention because most bacteria are located around the nail folds and most glove punctures occur at the fingertips. Friction is required to remove resident microorganisms that are attached by adhesion or adsorption, whereas transient bacteria are easily removed by simple hand washing.

Solutions containing either chlorhexidine gluconate or one of the iodophors are the most effective surgical scrub preparations and have the fewest problems with stability, contamination, and toxicity.⁹⁵ Alcohols applied to the skin are among the safest known antiseptics, and they produce the greatest and most rapid reduction in bacterial counts on clean skin.⁹⁶ All variables considered, chlorhexidine gluconate followed by an iodophor appears to be the best option [see Table 8].

The purpose of washing the hands after surgery is to remove microorganisms that are resident, that flourished in the warm, wet environment created by wearing gloves, or that reached the hands by entering through puncture holes in the gloves. On the ward, even minimal contact with colonized patients has been demonstrated to transfer microorganisms.⁹⁷ As many as 1,000 organisms were transferred by simply touching the patient's hand, taking a pulse, or lifting the patient. The organisms survived for 20 to 150 minutes, making their transfer to the next patient clearly possible.

A return to the ancient practice of washing hands between each patient contact is warranted. Nosocomial spread of numerous organisms—including *C. difficile*; MRSA, VRE, and other antibiotic-resistant bacteria; and viruses—is a constant threat.

Hand washing on the ward is complicated by the fact that overwashing may actually increase bacterial counts. Dry, damaged skin harbors many more bacteria than healthy skin and is almost impossible to render even close to bacteria free. Although little is known about the physiologic changes in skin that result from frequent washings, the bacterial flora is certainly modified by alterations in the lipid or water content of the skin. The so-called dry hand syndrome was the impetus behind the development of the alcohol-based gels now available. These preparations make it easy for surgeons to

Table 8 Characteristics of Three Topical Antimicrobial Agents Effective against Both Gram-Positive and Gram-Negative Bacteria⁹⁶

Agent	Mode of Action	Antifungal Activity	Comments
Chlorhexidine	Cell wall disruption	Fair	Poor activity against tuberculosis-causing organisms; can cause ototoxicity and eye irritation
Iodine/iodophors	Oxidation and substitution by free iodine	Good	Broad antibacterial spectrum; minimal skin residual activity; possible absorption toxicity and skin irritation
Alcohols	Denaturation of protein	Good	Rapid action but little residual activity; flammable

clean their hands after every patient encounter with minimal damage to their skin.

INFECTION PREVENTION IN BOWEL SURGERY

At present, the best method of preventing SSIs after bowel surgery is, once again, a subject of debate. There have been three principal approaches to this issue, involving mechanical bowel preparation in conjunction with one of the following three antibiotic regimens^{56,98–103}:

1. Oral antibiotics (usually neomycin and erythromycin),^{16–21,102}
2. Intravenous antibiotics covering aerobic and anaerobic bowel flora,^{16–21,56,100,101} or
3. A combination of regimens 1 and 2 (meta-analysis suggests that the combination of oral and parenteral antibiotics is best).¹⁰³

With respect to mechanical bowel preparation, there are now many trials that in modern times have failed to be supportive.^{16–19} Meta-analysis suggests no value in the prevention of infection and the possibility of increasing complications.^{16,21} The increased SSI and leak rates noted have been attributed to the complications associated with vigorous bowel preparation, leading to dehydration, overhydration, or electrolyte abnormalities.

An observational study reported a 26% SSI rate in colorectal surgery patients.¹⁰⁴ Intraoperative hypotension and body mass index were the only independent predictive variables. All patients underwent mechanical bowel preparation the day before operation and received oral antibiotics and perioperative IV antibiotics. Half of the SSIs were discovered after discharge. Most would agree that the protocol was standard. These and other results suggest that a fresh look at the infectious complications of surgery—and of bowel surgery in particular—is required.

INTEGRATION OF DETERMINANTS OF INFECTION

The significant advances in the control of wound infection during the past several decades are linked to a better understanding of the biology of wound infection, and this link has permitted the advance to the concept of SSI.² In all tissues at any time, there will be a critical inoculum of bacteria that would cause an infectious process [see Figure 3]. The standard definition of infection in urine and sputum has been 10^5 organisms/mL. In a clean dry wound, 10^5 bacteria produce a wound infection rate of 50% [see Figure 3].¹² Effective use of antibiotics reduces the infection rate to 10% with the same number of bacteria and thereby permits the wound to tolerate a much larger number of bacteria.

All of the clinical activities described are intended either to reduce the inoculum or to permit the host to manage the number of bacteria that would otherwise be pathologic. One study in guinea pigs showed how manipulation of local blood flow, shock, the local immune response, and foreign material can enhance the development of infection.¹⁰⁵ This study and two others defined an early decisive period of host antimicrobial activity that lasts for 3 to 6 hours after contamination.^{51,105,106} Bacteria that remain after this period are the infecting inoculum. Processes that interfere with this early response (e.g., shock, altered perfusion, adjuvants, or foreign material) or support it (e.g., antibiotics or total care) have a major influence on outcome.

One investigation demonstrated that silk sutures decrease the number of bacteria required for infection.¹⁰⁷ Other investigators used a suture as the key adjuvant in studies of host manipulation,¹⁰⁸ whereas a separate study demonstrated persistent susceptibility to wound infection days after shock.¹⁰⁹ The common variable is the number of bacteria. This relation may be termed the inoculum effect, and it has great relevance in all aspects of infection control. Applying knowledge of this effect in practical terms involves the following three steps:

1. Keeping the bacterial contamination as low as possible via asepsis and antisepsis, preoperative preparation of patient and surgeon, and antibiotic prophylaxis
2. Maintaining local factors in such a way that they can prevent the lodgment of bacteria and thereby provide a locally unreceptive environment
3. Maintaining systemic responses at such a level that they can control the bacteria that become established

These three steps are related to the determinants of infection and their applicability to daily practice. Year-by-year reductions in wound infection rates, when closely followed, indicate that it is possible for surgeons to continue improving results by attention to quality of clinical care and surgical technique, despite increasingly complex operations.^{5,14,29–31} In particular, the measures involved in the first step (control of bacteria) have been progressively refined and are now well established.

The integration of determinants has significant effects [see Figures 3 and 4]. When wound closure was effected with a wound hematocrit of 8% or more, the inoculum required to produce a wound infection rate of 40% was 100 bacteria [see Figure 3]. Ten bacteria produced a wound infection rate of 20%. The shift in the number of organisms required to produce clinical infection is significant. It is obvious that this inoculum effect can be changed dramatically by good surgical technique and further altered by use of prophylactic antibiotics. If the inoculum is always slightly smaller than the number of organisms required to produce infection in any given setting, the results are excellent. There is clearly a relation between the number of bacteria and the local environment. The local effect can also be seen secondary to systemic physiologic change, specifically shock. One study showed the low local perfusion in shock to be important in the development of an infection.^{105,106}

One investigation has shown that shock can alter infection rates immediately after its occurrence [see Figure 4].¹⁰⁹ Furthermore, if the inoculum is large enough, antibiotics will not control bacteria. In addition, there is a late augmentation of infection lasting up to 3 days after restoration of blood volume. These early and late effects indicate that systemic determinants come into play after local effects are resolved. These observations call for further study, but, obviously, the combined abnormalities alter the outcome.

Systemic host responses are important for the control of infection. The patient has been clearly implicated as one of the four critical variables in the development of wound infection.⁶ In addition, the bacterial inoculum, the location of the procedure and its duration, and the coexistence of three or more diagnoses were found to give a more accurate prediction of the risk of wound infection. The spread of risk is defined better with the SENIC index (1 to 27%) than it

is with the traditional classification (2.9 to 12.6%). The importance of the number of bacteria is lessened if the other factors are considered in addition to inoculum. The inoculum effect has to be considered with respect to both the number of organisms and the local and systemic host factors that are in play. Certain variables were found to be significantly related to the risk of wound infection in three important prospective studies.^{6,11,13} It is apparent that the problem of SSI cannot be examined only with respect to the management of bacteria. Host factors have become much more significant now that the bacterial inoculum can be maintained at low levels by means of asepsis, antisepsis, technique, and prophylactic antibiotics.¹¹⁰

Important host variables include the maintenance of normal homeostasis (physiology) and immune response. Maintenance of normal homeostasis in patients at risk is one of the great advances of surgical critical care.¹¹⁰ The clearest improvements in this regard have come in maintenance of blood volume, oxygenation, and oxygen delivery.

One group demonstrated the importance of oxygen delivery, tissue perfusion, and P_{aO_2} in the development of wound infection.¹¹¹ Oxygen can have as powerful a negative influence on the development of SSI as antibiotics can.¹¹² The

influence is very similar to that seen in other investigations. Whereas a P_{aO_2} equivalent to a true fractional concentration of oxygen in inspired gas (F_{IO_2}) of 45% is not feasible, maintenance, when appropriate, of an increased F_{IO_2} in the postoperative period may prove an elementary and effective tool in managing the inoculum effect.

Modern surgical practice has reduced the rate of wound infection significantly. Consequently, it is more useful to think in terms of SSI, which is not limited to the incision but may occur anywhere in the operative field; this concept provides a global objective for control of infections associated with a surgical procedure. Surveillance is of great importance for quality assurance. Reports of recognized pathogens (e.g., *S. epidermidis* and group A streptococci) and unusual organisms (e.g., *Rhodococcus* [Gordona] *bronchialis*, *Mycoplasma hominis*, and *Legionella dumoffii*) in SSIs highlight the importance of infection control and epidemiology for quality assurance in surgical departments.^{22-24,27,28} (Although these reports use the term *wound infection*, they are addressing what we now call SSI.) The importance of surgeon-specific and service-specific SSI reports should be clear [see Table 6]^{13,14,113} and their value in quality assurance evident.

2 INFECTION CONTROL IN SURGICAL PRACTICE

Vivian G. Loo, MD, MSc, FRCPC

Surgical procedures, by their very nature, interfere with the normal protective skin barrier and expose the patient to microorganisms from both endogenous and exogenous sources. Infections resulting from this exposure may not be limited to the surgical site but may produce widespread systemic effects. Prevention of surgical site infections (SSIs) is therefore of primary concern to surgeons and must be addressed in the planning of any operation. Standards of prevention have been developed for every step of a surgical procedure to help reduce the impact of exposure to microorganisms.¹⁻³ Traditional control measures include sterilization of surgical equipment, disinfection of the skin, use of prophylactic antibiotics, and expeditious operation.

The Study on the Efficacy of Nosocomial Infection Control (SENIC), conducted in US hospitals between 1976 and 1986, showed that surgical patients were at increased risk for all types of infections. The nosocomial, or hospital-acquired, infection rate at that time was estimated to be 5.7 cases out of every 100 hospital admissions.⁴ These infections included surgical site infections (SSIs), as well as bloodstream, urinary, and respiratory infections. Today, the increased use of minimally invasive surgical procedures and early discharge from the hospital necessitates postdischarge surveillance⁵ in addition to in-hospital surveillance for the tracking of nosocomial infections. With the reorganization of health care delivery programs, nosocomial infections will appear more frequently in the community and should therefore be considered a part of any patient care assessment plan.

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) strongly recommends that the reduction of healthcare associated infections be prioritized as a national patient safety goal (<http://www.jointcommission.org/PatientSafety/InfectionControl>). Effective infection control and prevention require an organized, hospital-wide program aimed at achieving specific objectives. The program's purpose should be to obtain relevant information on the occurrence of nosocomial infections among both patients and employees. The data should be documented, analyzed, and communicated along with a plan for corrective measures. Such surveillance activities, combined with education, form the basis of an infection control program.

Data relating to host factors are an integral part of infection data analysis. Documentation of host factors has made for a better appreciation of the associated risks and has allowed comparative evaluation of infection rates. Development of new surgical equipment and technological advances have influenced the impact of certain risk factors, such as the length of an operation and the duration of a hospital stay. Clinical investigations have helped improve the

understanding of host factors and have influenced other aspects of surgical practice.⁶⁻¹¹ Excessive use of and reliance on antibiotics have led to the emergence of multidrug-resistant microorganisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA), glycopeptide-intermediate *S. aureus* (GISA), multidrug-resistant *Mycobacterium tuberculosis*, and multidrug-resistant *Enterococcus* strains.¹²⁻¹⁵ Such complications reemphasize the need to focus on infection control as an essential component of preventive medicine.

Besides the impact of morbidity and mortality on patients, there is the cost of treating nosocomial infections, which is a matter of concern for surgeons, hospital administrators, insurance companies, and government planners alike. Efforts to reduce the occurrence of nosocomial infections are now a part of hospital cost-control management programs.^{16,17} The challenge to clinicians is how to reduce cost while maintaining control over, and preventing spread of, infection. A review of 30 studies published between 1990 and 2003 reported that approximately 20% of nosocomial infections were preventable.¹⁸

The Surgical Wound and Infection Control

NOSOCOMIAL INFECTIONS AND SURGICAL SITE INFECTIONS

Nosocomial infections are defined as infections acquired in the hospital. There must be no evidence that the infection was present or incubating at the time of hospital admission. Usually, an infection that manifests 48 to 72 hours after admission is considered to be nosocomially acquired. An infection that is apparent on the day of admission is usually considered to be community acquired, unless it is epidemiologically linked to a previous admission or to an operative procedure at the time of admission.

SSIs account for 14 to 16% of all nosocomial infections. They occur in 2 to 5% of patients undergoing clean procedures and in as many as 20% of patients undergoing intra-abdominal operations.¹⁹ To encourage a uniform approach among data collectors, the Centers for Disease Control and Prevention (CDC) has suggested three categories of SSIs, supplying definitions for each category [see Table 1].²⁰ The CDC defines an incisional SSI as an infection that occurs at the incision site within 30 days after surgery or within 1 year if a prosthetic implant is in place. Infection is characterized by redness, swelling, or heat with tenderness, pain, or dehiscence at the incision site and by purulent drainage. Other indicators of infection include fever, deliberate opening of the wound, culture-positive drainage, and a physician's diagnosis of infection with prescription of antibiotics. The category of

Table 1 Surgical Site Infections (SSIs)²⁰

Superficial SSIs
Skin
Deep incisional SSIs
Fascia
Muscle layers
Organ or space SSIs
Body organs
Body spaces

organ or space SSI was included to cover any part of the anatomy other than the incision (ie, organs or spaces) that might have been opened or manipulated during the operative procedure. This category would include, for example, arterial and venous infections, endometritis, disk space infections, and mediastinitis.²⁰

There should be collaboration between the physician or nurse and the infection control practitioner to establish the presence of an SSI. The practitioner should complete the surveillance with a chart review and document the incident in a computer database program for analysis. The data must be systematically recorded; many commercial computer programs are available for this purpose. One group reported that their experience with the Health Evaluation through Logical Processing system was useful for identifying patients at high risk for nosocomial infections.²¹

IDENTIFICATION OF RISK FACTORS

The risk of development of an SSI depends on host factors, perioperative wound hygiene, and the duration of the surgical procedure. Identification of host and operative risk factors can help determine the potential for infection and point toward measures that might be necessary for prevention and control.

Host Risk Factors

Host susceptibility to infection can be estimated according to the following variables: older age, severity of disease, physical-status classification (see below), prolonged preoperative hospitalization, morbid obesity, malnutrition, immunosuppressive therapy, smoking, preoperative colonization with *S. aureus*, and coexistent infection at a remote body site.²²

A scale dividing patients into five classes according to their physical status was introduced by the American Society of Anesthesiologists (ASA) in 1974 and tested for precision in 1978.²³ The test results showed that the ASA scale is a workable system, though it lacks scientific definition [see Table 2].

Significant differences in infection rates have been shown in patients with different illnesses. In one prospective study, the severity of underlying disease (rated as fatal, ultimately fatal, or nonfatal) was shown to have predictive value for endemic nosocomial infections; the nosocomial infection rate in patients with fatal diseases was 23.6%, compared with 2.1% in patients with nonfatal diseases.²⁴

Operative Risk Factors

Several factors related to the operative procedure may be associated with the risk of development of an SSI [see 1:1 *Prevention of Postoperative Infection*]. These include method of

Table 2 American Society of Anesthesiologists Physical Status Scale

Class	Patient Description
1	A normally healthy individual
2	A patient with mild systemic disease
3	A patient with severe systemic disease that is not incapacitating
4	A patient with incapacitating systemic disease that is a constant threat to life
5	A moribund patient who is not expected to survive 24 hr with or without operation
E	Added for emergency procedures

hair removal (and likelihood of consequent skin injury), inappropriate use of antimicrobial prophylaxis, duration of the operation, and wound classification. The influence of hair removal methods on SSI has been examined by many investigators. Infection rates were reported to be lower with depilatory agents and electric clippers than with razors.^{6,7} Antimicrobial prophylaxis is used for all operations that involve entry into a hollow viscus. Antimicrobial prophylaxis is also indicated for clean operations in which an intra-articular or intravascular prosthetic device will be inserted and for any operation in which an SSI would have a high morbidity.²² A comprehensive study determined that there is considerable variation in the timing of administration of prophylactic antibiotics, but that administration within 2 hours before surgery reduces the risk of SSI.⁸

Operative wounds are susceptible to varying levels of bacterial contamination, by which they are classified as clean, clean-contaminated, contaminated, or dirty.²⁵ In most institutions, the responsibility for classifying the incision site is assigned to the operating room circulating nurse; one assessment suggests that the accuracy of decisions made by this group is as high as 88%.²⁶

Composite Risk Indices

The CDC established the National Nosocomial Infections Surveillance (NNIS) system in 1970 to create a national database of nosocomial infections.²⁷ The NNIS system has been used to develop definitions of infections and indices for predicting the risk of nosocomial infection in a given patient. The NNIS system has been integrated into the National Healthcare Safety Network (NHSN).²⁸

NNIS Basic Risk Index NNIS developed a composite risk index composed of the following criteria: ASA score, wound class, and duration of surgery. Reporting on data collected from 44 US hospitals between 1987 and 1990, NNIS demonstrated that this risk index is a significantly better predictor for development of SSI than the traditional wound classification system alone.^{29,30} The NNIS risk index is a useful method of risk adjustment for a wide variety of procedures.

The NNIS risk index assigns patients scores of 0, 1, 2, or 3. A patient's score is determined by counting the number of risk factors present from among the following: an ASA score of 3, 4, or 5; a surgical wound that is classified as

contaminated or dirty/infected; and an operation lasting longer than T hours (where T represents the 75th percentile of distribution of the duration of the operative procedure being performed, rounded to the nearest whole number of hours).

Modified NNIS Basic Risk Index for Procedures Using Laparoscopes For cholecystectomy and colon surgery procedures, the use of a laparoscope lowered the risk of SSI within each NNIS risk index category.³¹ Hence, for these procedures, when the procedure is performed laparoscopically, the risk index should be modified by subtracting 1 from the basic NNIS risk index score. With this modification, the risk index has values of M (or -1), 0, 1, 2, or 3. For appendectomy and gastric surgery, use of a laparoscope affected SSI rates only when the NNIS basic risk index was 0, thereby yielding five risk categories: 0—Yes, 0—No, 1, 2, and 3, where Yes or No refers to whether the procedure was performed with a laparoscope.³¹

Operation-Specific Risk Factors It is likely that operation-specific logistic regression models will increasingly be used to calculate risk. For example, in spinal fusion surgery, Richards and colleagues identified diabetes mellitus, ASA score greater than 3, operation duration longer than 4 hours, and posterior surgical approach as significant independent predictors of SSI.³² Other logistic regression models have been developed for craniotomy and cesarean section.^{33,34} These models should permit more precise risk adjustment.

PREVENTIVE MEASURES

In any surgical practice, policies and procedures should be in place pertaining to the making of a surgical incision and the prevention of infection. These policies and procedures should govern the following: (1) skin disinfection and hand-washing practices of the operating team, (2) preoperative preparation of the patient's skin (e.g., hair removal and use of antiseptics), (3) the use of prophylactic antibiotics, (4) techniques for preparation of the operative site, (5) management of the postoperative site if drains, dressings, or both are in place, (6) standards of behavior and practice for the operating team (e.g., the use of gown, mask, and gloves), (7) special training of the operating team, and (8) sterilization and disinfection of instruments.

Surgical Infection Prevention and Surgical Care Improvement Projects

In 2002, the Centers for Medicare and Medicaid Services, in collaboration with the CDC, implemented the National Surgical Infection Prevention (SIP) Project.³⁵ The goal of the SIP Project is to decrease the morbidity and mortality associated with postoperative SSI by advocating appropriate selection and timing of prophylactic antibiotics. Three performance measures were developed: (1) the percentage of patients who receive parenteral antimicrobial prophylaxis within 1 hour before incision (within 2 hours for vancomycin or fluoroquinolone), (2) the percentage of patients who are given a prophylactic antimicrobial regimen consistent with published guidelines, and (3) the percentage of patients whose prophylactic antimicrobial is discontinued within 24 hours after surgery. These three performance measures were

the focus of improvement in a 1-year collaborative project that included 56 hospitals and 43 Medicare quality improvement organizations.³⁶ Other performance measures included maintenance of patient normothermia, use of supplemental oxygenation, maintenance of euglycemia and appropriate hair removal. In this collaborative project, hospitals reported a 27% mean reduction in their SSI rates.³⁶

The Surgical Care Improvement Project (SCIP) was developed in 2003 and evolved from the SIP project.³⁵ This initiative is a national partnership of organizations (including the American College of Surgeons [ACS]) that is committed to the reduction of postoperative complications in four areas: (1) prevention of SSIs, (2) prevention of venous thromboembolism, (3) prevention of adverse cardiac events, and (4) prevention of respiratory complications.³⁵

Hand Hygiene

Although hand hygiene is considered the single most important measure for preventing nosocomial infections, poor compliance is frequent.³⁷ Role modeling is important in positively influencing this behavior. One study showed that a hand-washing educational program contributed to a reduction in the rate of nosocomial infections.³⁸ Good hand-washing habits can be encouraged by making facilities (with sink, soap, and paper towels) visible and easily accessible in patient care areas [see 1:1 *Prevention of Postoperative Infection*].

Agents used for hand hygiene include plain nonantimicrobial soaps, antimicrobial soaps, and waterless alcohol-based hand antiseptics. Plain soaps have very little antimicrobial activity; they mainly remove dirt and transient flora.³⁹ Compared with plain soaps, antimicrobial soaps achieve a greater log reduction in eliminating transient flora and have the additional advantage of sustained activity against resident hand flora.³⁹ Alcohol-based hand antiseptics have an excellent spectrum of antimicrobial activity and rapid onset of action, dry rapidly, and do not require the use of water or towels.⁴⁰ Therefore, they are recommended for routine decontamination of hands during patient care, except when hands are visibly soiled. Emollients are often added to alcohol-based waterless hand antiseptics because of these antiseptics' tendency to cause drying of the skin.⁴⁰

Sterilization and Disinfection

Spaulding proposed in 1972 that the level of disinfection and sterilization for surgical and other instruments be determined by classifying the instruments into three categories according to the degree of infection risk involved in their use: critical, semicritical, and noncritical.⁴¹

Critical items include objects or instruments that directly enter the vascular system or sterile areas of the body. These items should be sterilized by steam under pressure, dry heat, ethylene oxide, or other approved methods. Flash sterilization is the process by which surgical instruments are sterilized for immediate use should an emergency situation arise (e.g., an instrument that was accidentally dropped). This is usually achieved by leaving instruments unwrapped in a container and using a rapid steam cycle.⁴² Instruments must still be manually cleaned, decontaminated, inspected, and properly arranged in the container before sterilization. Implantables should not be flash sterilized. Flash sterilization is not intended

to replace conventional steam sterilization of surgical instruments or to reduce the need for adequate instrument inventory.⁴²

Semicritical items are those that come into contact with mucous membranes or skin that is not intact (eg, bronchoscopes and gastroscopes). Scopes have the potential to cause infection if they are improperly cleaned and disinfected. Transmission of infection has been documented after endoscopic investigations, including infection with *Salmonella typhi* and *Helicobacter pylori*.^{43,44} Semicritical items generally require high-level disinfection that kills all microorganisms except bacterial spores.⁴⁵ Glutaraldehyde 2% is a high-level disinfectant that has been used extensively in flexible endoscopy. Before disinfection, scopes should receive a thorough manual cleaning to eliminate gross debris. To achieve high-level disinfection, the internal and external surfaces and channels should come into contact with the disinfecting agent for a minimum of 20 minutes.⁴⁵ Glutaraldehyde has certain disadvantages. In particular, it requires activation before use; moreover, it is irritating to the skin, eyes, and nasal mucosa, and thus, its use requires special ventilation or a ducted fume hood.⁴⁵ An alternative to glutaraldehyde is orthophthalaldehyde (OPA), a newer agent that is approved by the Food and Drug Administration (FDA) for high-level disinfection. OPA is odorless and nonirritating and does not require activation before use.⁴⁶

Noncritical items are those that come in contact with intact skin (e.g., blood pressure cuffs). They require only cleaning with a detergent and warm water or disinfection with an intermediate-level or low-level germicide for 10 minutes.

The reuse of single-use medical devices has become a topic of interest because of the implied cost savings. The central concerns are the effectiveness of sterilization or disinfection according to category of use, as well as maintenance of the essential mechanical features and the functional integrity of the item to be reused. The FDA has issued regulations governing third-party and hospital reproducers engaged in reprocessing single-use devices for reuse. These regulations are available on the FDA's Web site (<http://www.fda.gov/cdrh/reprocessing/index.html>).

Hair Removal

An infection control program should have a hair-removal policy for preoperative skin preparation [see 1:1 *Prevention of Postoperative Infection*].

Operating Room Environment

Environmental controls in the OR have been used to reduce the risk of SSI [see 1:8 *Preparation of the Operating Room*]. The OR should be maintained under a positive pressure of at least 2.5 Pa in relation to corridors and adjacent areas. In addition, there should be 20 to 25 air changes per hour for ceiling heights between 9 and 12 feet.⁴⁷

HEALTH STATUS OF THE HEALTH CARE TEAM

The health care team has a primary role in the prevention of infection. Continued education and reinforcement of policies are essential: the team must be kept well informed and up to date on concepts of infection control. Inadvertently, team members may also be the source of, or the vector in, transmission of infection. Nosocomial infection outbreaks

with MRSA have been traced to MRSA carriers among health care workers.⁴⁸ Screening of personnel to identify carriers is undertaken only when an outbreak of nosocomial infection occurs that cannot be contained despite implementation of effective control measures and when a health care worker is epidemiologically linked to cases.

Protecting the health care team from infection is a constant concern. Preventive measures, such as immunizations and preemployment medical examinations, should be undertaken at an employee health care center staffed by knowledgeable personnel.⁴⁹ Preventable infectious diseases, such as chickenpox and rubella, should be tightly controlled in hospitals that serve immunocompromised and obstetric patients. It is highly recommended that a record be maintained of an employee's immunizations. Knowledge of the employee's health status on entry to the hospital helps ensure appropriate placement and good preventive care.

When exposure to contagious infections is unavoidable, susceptible personnel should be located, screened, and given prophylactic treatment if necessary. In collaboration with the occupational health department, infection control personnel should define the problem, establish a definition of contact, and take measures to help reduce panic.

Isolation Precautions

CDC guidelines have been developed to prevent the transmission of infections.⁵⁰ These isolation guidelines promote two levels of isolation precautions: standard precautions and transmission-based precautions.

Standard Precautions The standard precautions, which incorporate the main features of the older universal precautions and body substance isolation guidelines, were developed to reduce the risk of transmission of microorganisms for all patients, regardless of their diagnosis.^{50,51} Standard precautions apply to blood, all body fluids, secretions and excretions, and mucous membranes.

Transmission-Based Precautions Transmission-based precautions were developed for certain epidemiologically important pathogens or clinical presentations. These precautions comprise three categories, based on the mode of transmission: airborne precautions, droplet precautions, and contact precautions.⁵⁰ Precautions may be combined for certain microorganisms or clinical presentations (e.g., both contact and airborne precautions are indicated for a patient with varicella).

Airborne precautions are designed to reduce transmission of microorganisms spread via droplets that have nuclei 5 μ m in size or smaller, remain suspended in air for prolonged periods of time, and have the capability of being dispersed widely.⁵⁰ Airborne precautions include wearing an N95 respirator, placing the patient in a single room that is under a negative pressure of 2.5 Pa in relation to adjacent areas, keeping the door closed, providing a minimum of 6 to 12 air changes per hour, and exhausting room air outside the building and away from intake ducts or, if recirculated, through a high-efficiency particulate air (HEPA) filter.⁵⁰ Airborne precautions are indicated for patients with suspected or confirmed infectious pulmonary or laryngeal tuberculosis; measles; varicella; disseminated herpes zoster; and Lassa,

Ebola, Marburg, and other hemorrhagic fevers with pneumonia. Varicella, disseminated herpes zoster, and hemorrhagic fevers with pneumonia also call for contact precautions (see below).

Droplet precautions are designed to reduce the risk of transmission of microorganisms spread via large-particle droplets that are greater than 5 μm in size, do not remain suspended in the air for prolonged periods, and usually travel 1 m or less.⁵⁰ No special ventilation requirements are required to prevent droplet transmission. A single room is preferable, and the door may remain open. Examples of patients for whom droplet precautions are indicated are those with influenza, rubella, mumps, and meningitis caused by *Haemophilus influenzae* and *Neisseria meningitidis*.

Contact precautions are designed to reduce the risk of transmission of microorganisms by direct or indirect contact. Direct contact involves skin-to-skin contact resulting in physical transfer of microorganisms.⁵⁰ Indirect contact involves contact with a contaminated inanimate object that acts as an intermediary. Contact precautions are indicated for patients colonized or infected with *Clostridium difficile* and multidrug-resistant bacteria that the infection control program judges to be of special clinical and epidemiologic significance.⁵⁰

Exposure to Bloodborne Pathogens

The risk of transmission of HIV and hepatitis B virus (HBV) from patient to surgeon or from surgeon to patient has resulted in a series of recommendations governing contact with blood and body fluids.⁵²⁻⁵⁴ The risk of acquiring a bloodborne infection (e.g., HBV, hepatitis C virus [HCV], or HIV) depends on three factors: type of exposure to the bloodborne pathogen, prevalence of infection in the population, and the rate of infection after exposure to the bloodborne pathogen.⁵²⁻⁵⁴ Postexposure management has been discussed in CDC guidelines (<http://www.cdc.gov/mmwr/pdf/rr/rr5011.pdf>).⁵² Management of occupational exposures to HIV was updated in 2005 (<http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5409a1.htm>).⁵⁴

Protection of the face and hands during the operative procedure is important. A study of 8,502 operations found that the rate of direct blood exposure was 12.4%, whereas the rate of parenteral exposure via puncture wounds and cuts was 2.2%. Parenteral blood contacts were twice as likely to occur among surgeons as among other OR personnel.⁵⁵ These findings support the need for OR practice policies and the choice of appropriate personal protective equipment for the OR staff. OR practice policy should give particular attention to methods of using sharp instruments and to ways of reducing the frequency of percutaneous injuries: sharp instruments should be passed in a metal dish, cautery should be used, and great care should be taken in wound closures. It is important that face shields and masks protect the operating team from splashes and aerosolized fluids. For optimal protection, a mask should be fluid-capture efficient and air resistant.⁵⁶

For invasive surgical procedures, double gloving has become routine. However, there are recognized differences among the gloves available. Latex allergy is an important issue; nonlatex alternatives are available for those who are allergic.

Hepatitis B Virus For active surgeons and other members of the health care team, HBV infection continues to

pose a major risk. It is estimated that in the United States, about 1.25 million people have chronic HBV infection, and more than 4 million have chronic HCV infection. Transmission of these infections to health care workers continues to occur, and each year, approximately 250 health care workers die of chronic HBV infection alone.⁵⁷ Hepatitis B vaccination has proved safe and protective and is highly recommended for all high-risk employees; it should be made available through the employee health care center.

Despite the efficacy of the vaccine, many surgeons and other personnel remain unimmunized and are at high risk for HBV infection.⁵⁷ Whereas younger surgeons have been routinely immunized, an estimated 25 to 30% of surgeons who have been in practice for longer than 10 to 15 years remain at substantial risk.⁵⁷ HBV is far more easily transmitted than HIV and continues to have a greater impact on the morbidity and mortality of health care personnel.⁵³ The risk of seroconversion is at least 30% after percutaneous exposure to blood from a hepatitis B e antigen-seropositive source.⁵³ Given that a patient's serostatus may be unknown, it is important that health care workers follow standard precautions for all patients.

Hepatitis C Virus The average incidence of seroconversion after percutaneous exposure from an HCV-positive source is 1.8% (range, 0 to 7%).^{53,58,59} Mucous membrane exposure to blood rarely results in transmission, and no transmission has been documented from exposure of intact or nonintact skin to blood.⁵³ There is no recommended postexposure prophylaxis regimen for HCV. The use of immunoglobulin has not been demonstrated to be protective.⁵³ There are no antiviral medications recommended for postexposure prophylaxis.⁵³

Human Immunodeficiency Virus Exposure to blood and body substances of patients who have AIDS or who are seropositive for HIV constitutes a health hazard to hospital employees. The magnitude of the risk depends on the degree and method of exposure [see 8:21 *Acquired Immunodeficiency Syndrome*].⁵⁴ Because screening for HIV infection is not mandatory among patients, the CDC recommends following the same guidelines for all patients undergoing invasive procedures that one would use in cases of known HIV-infected patients [see Table 3].⁵²

There have been isolated reports of transmission of HIV, HBV, and HCV from healthcare workers to patients. It is imperative to prevent transmission of these bloodborne pathogens from surgeons to patients. Accordingly, the CDC has developed specific guidelines for health care workers and exposure-prone activities [see Table 3].⁵² Similarly, the ACS has issued additional recommendations regarding the surgeon's role in the prevention of hepatitis transmission and HIV [see Table 4].^{52,57,60}

Exposure to Tuberculosis

In studies of health care workers, the incidence of positive results on tuberculin skin testing have ranged from 0.11 to 10%.^{61,62} Health care workers who are immunocompromised are at high risk for the development of disease after exposure.⁶¹

Table 3 CDC Recommendations for Prevention of HIV and HBV Transmission during Invasive Procedures⁵²

Health care workers with exudative lesions or weeping dermatitis should cover any unprotected skin, or they should not provide patient care until the damaged skin has healed.
Hands should be washed after every patient contact.
Health care workers should wear gloves when contact with blood or body substances is anticipated; double gloves should be used during operative procedures; hands should be washed after gloves are removed.
Gowns, plastic aprons, or both should be worn when soiling of clothing is anticipated.
Mask and protective eyewear or face shield should be worn if aerosolization or splattering of blood or body substances is expected.
Resuscitation devices should be used to minimize the need for mouth-to-mouth resuscitation.
Disposable containers should be used to dispose of needles and sharp instruments.
Avoid accidents and self-wounding with sharp instruments by following these measures:

- Do not recap needles.
- Use needleless systems when possible.
- Use cautery and stapling devices when possible.
- Pass sharp instruments in metal tray during operative procedures.

In the case of an accidental spill of blood or body substance on skin or mucous membranes, do the following:

- Rinse the site immediately and thoroughly under water.
- Wash the site with soap and water.
- Document the incident (i.e., report to Occupational Safety and Health Administration or to the Infection Control Service).

Blood specimens from all patients should be considered hazardous at all times.
Prompt attention should be given to spills of blood or body substances, which should be cleaned with an appropriate disinfectant.

CDC = Centers for Disease Control and Prevention; HBV = hepatitis B virus.

The CDC recommendations for tuberculosis prevention place emphasis on a hierarchy of control measures, including administrative engineering controls and personal respiratory protection (<http://www.cdc.gov/mmwr/PDF/rr/rr5417.pdf>).⁶³ The following measures should be considered:

1. The use of risk assessments and development of a written tuberculosis control protocol.
2. Early identification, treatment, and use of airborne precautions for persons who have tuberculosis.
3. Tuberculosis screening and respiratory protection programs for health care workers.
4. Training and education.
5. Evaluation of tuberculosis infection control programs.⁶³

Activities of an Infection Control Program

SURVEILLANCE

The cornerstone of an infection control program is surveillance. This process depends on the verification, classification, analysis, reporting, and investigation of infection occurrences, with the intent of generating or correcting policies and procedures. Five surveillance methods can be applied^{64,65}:

1. Total, or hospital-wide, surveillance: collection of comprehensive data on all infections in the facility, with the aim of correcting problems as they arise. This is labor intensive.

Table 4 ACS Recommendations for Preventing Transmission of Hepatitis⁵⁷

Surgeons should continue to utilize the highest standards of infection control, involving the most effective known sterile barriers, universal precautions, and scientifically accepted measures to prevent blood exposure during every operation. This practice should extend to all sites where surgical care is rendered and should include safe handling practices for needles and sharp instruments.
Surgeons have the same ethical obligations to render care to patients with hepatitis as they have to render care to other patients.
Surgeons with natural or acquired antibodies to HBV are protected from acquiring HBV from patients and cannot transmit the disease to patients. All surgeons and other members of the health care team should know their HBV immune status and become immunized as early as possible in their medical career.
Surgeons without evidence of immunity to HBV who perform procedures should know their HBsAg status and, if this is positive, should also know their HBeAg status. In both instances, expert medical advice should be obtained and all appropriate measures taken to prevent disease transmission to patients. Medical advice should be rendered by an expert panel composed and convened to fully protect practitioner confidentiality. The HBeAg-positive surgeon and the panel should discuss and agree on a strategy for protecting patients at risk for disease transmission.
On the basis of current information, surgeons infected with HCV have no reason to alter their practice but should seek expert medical advice and appropriate treatment to prevent chronic liver disease.

HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HCV = hepatitis C virus

2. Surveillance by objective, or targeted surveillance, in which a specific goal is set for reducing certain types of infection. This concept is priority directed and can be further subdivided into two distinct activities:
 - a. The setting of outcome objectives, in which the objectives for the month or year are established and all efforts are applied to achieving a desired rate of infection. As with the hospital-wide approach, a short-term plan would be made to monitor, record, and measure infections and to provide feedback on the results.
 - b. The setting of process objectives, which incorporates the patient care practices of doctors and nurses as they relate to outcome (e.g., wound infections and their control).
3. Periodic surveillance: intensive surveillance of infections and patient-care practices by unit or by service at different times of the year.
4. Prevalence survey: the counting and analysis of all active infections during a specified time period. This permits identification of nosocomial infection trends and problem areas.
5. Outbreak surveillance: the identification and control of outbreaks of infection. Identification can be made on the basis of outbreak thresholds if baseline bacterial isolate rates are available and outbreak thresholds can be developed. Problems are evaluated only when the number of isolates of a particular bacterial species exceeds outbreak thresholds.

Surveillance techniques include the practice of direct patient observation and indirect observation by review of microbiology reports, nursing Kardex, or the medical record

to obtain data on nosocomial infections.^{6,64} The sensitivity of case finding was found to be 33 to 65% with microbiology reports, 85% with Kardex, and 90% with total chart review.⁶⁴ These methods may be used either separately or in combination to obtain data on clinical outcomes.

The increasing practice of same-day or short-stay surgical procedures has led to the need for postdischarge surveillance. This may be done by direct observation in a follow-up clinic, by surveying patients through the mail or over the telephone, by reviewing medical records, or by mailing questionnaires directly to surgeons. The original CDC recommendation of 30 days for follow-up was used by one hospital to randomly screen post-joint arthroplasty patients by telephone. This screening identified an infection rate of 7.5%, compared with 2% for hospitalized orthopedic patients.⁶⁶ Results from another medical center suggested that 90% of cases would be captured in a 21-day postoperative follow-up program.⁵ The use of prosthetic materials for implants requires extending the follow-up period to 1 year.

Verification and Definition of Infection

The CDC provides definitions for specific nosocomial infections (<http://www.cdc.gov/ncidod/dhqp/pdf/nnis/NosInfDefinitions.pdf>).⁶⁷ The use of standardized definitions is critical for consistency, particularly if interhospital comparisons are made. A complete assessment should include clinical evaluation of commonly recognized sites (e.g., wound, respiratory system, urinary tract, and intravenous access sites) for evidence of infection, especially when no obvious infection is seen at the surgical site. Laboratory and radiologic data should complement the clinical information. Microbiologic evaluation should aim at identification of the microorganism (which depends on an adequate specimen for Gram's staining and culture).

Use of Denominators

The choice of denominators depends on the patients at risk of acquiring nosocomial infections and on the ease or difficulty of collecting the data for denominators. Commonly used denominators include the number of admissions, the number of patient-days, and the number of procedures. For device-related infections, the appropriate denominator is the number of days of device exposure; this variable takes into account the differences in the risks experienced by the monitored patient.

Data Analysis

The original practice of presenting overall hospital-wide crude rates provided little means for adjustment of variables (e.g., risk related to the patient or to the operation). The following three formulas, however, are said to offer more precision than traditional methods⁶⁸:

$$\begin{aligned} & \text{(Number of nosocomial infections/Service operations)} \\ & \quad \times 100 \\ & \text{[Number of site-specific nosocomial infections/Specific} \\ & \quad \text{operations (e.g., number of inguinal hernias)]} \times 100 \\ & \text{[Number of nosocomial infections/Hospital} \\ & \quad \text{admissions (patient-days)]} \times 1,000 \end{aligned}$$

Data on infections of the urinary tract, respiratory system, and circulatory system resulting from exposure to devices

such as Foley catheters, ventilators, and intravascular lines can be illustrated as device-associated risks according to site, as follows:

$$\begin{aligned} & \text{(Number of device-associated infections of a site/} \\ & \quad \text{Number of device days)} \times 1,000 \end{aligned}$$

Reporting

One use of surveillance data is to generate information for individual surgeons, service chiefs, and nursing personnel as an indicator of their progress in keeping infections and diseases under control. Infection notification to surgeons has been shown to have a positive influence on clean-wound infection rates.^{6,7} This technique was used by Cruse and Foord in 1980 to show a progressive decrease in the infection rates of clean surgical wounds to less than 1% over 10 years.⁷ In other settings, endemic rates of bloodstream, respiratory, and urinary tract infection were corrected and reduced by routine monitoring and reporting to medical and nursing staff.²⁴

In a medical setting, Britt and colleagues also reported a reduction in endemic nosocomial infection rates for urinary tract infections, from 3.7% to 1.3%, and for respiratory tract infections, from 4.0% to 1.6%, simply by keeping medical personnel aware of the rates.²⁴

Outbreak Investigation

There are 10 essential components to an outbreak investigation:

1. Verify the diagnosis and confirm that an outbreak exists. This is an important step, because other factors may account for an apparent increase in infections. These factors may include a reporting artifact resulting from a change in surveillance methodology, a laboratory error or change in laboratory methodology, or an increase in the denominator of the formula used for data analysis (if this increase is proportionate to the rise in the numerator, the infection rate has not changed).
2. Formulate a case definition to guide the search for potential patients with disease.
3. Draw an epidemic curve that plots cases of the disease against time of onset of illness. This curve compares the number of cases during the epidemic period with the baseline. In addition, the epidemic curve helps to determine the probable incubation period and how the disease is being transmitted (i.e., a common source versus person to person).
4. Review the charts of case patients to determine demographics and exposures to staff, medications, therapeutic modalities, and other variables of importance.
5. Perform a line listing of case patients to determine whether there is any common exposure.
6. Calculate the infection rate. The numerator is the number of infected patients, and the denominator is the number of patients at risk.
7. Formulate a tentative hypothesis to explain the reservoir and the mode of transmission. A review of the literature on similar outbreaks may be necessary.
8. Test the hypothesis, using a case-control study, cohort study, prospective intervention study, or microbiologic study. A case-control study is usually used, because it is less labor intensive. For a case-control study, control

subjects should be selected from an uninfected surgical population of patients who were hospitalized at the same time as those identified during the epidemic period and matched for age, gender, service operation, operation date, and health status (ASA score). Two or three control patients are usually selected for every case patient. The cases and controls are then compared with respect to possible exposures that may increase the risk of disease. Patient, personnel, and environmental microbiologic isolates (if any) should be kept for fingerprinting (e.g., with pulsed-field gel electrophoresis or random amplified polymorphic DNA polymerase chain reaction).

9. Institute infection control measures. This may be done at any time during the investigation. The control measures should be reviewed after institution to determine their efficacy and the possible need for changing them.
10. Report the incident to the infection control committee, and submit a report at the completion of the investigation. The administrators, physicians, and nurses involved should be informed and updated as events change.⁶⁹

ANTIMICROBIAL-RESISTANT MICROORGANISMS

Staphylococci

Hospitals and communities worldwide are facing the challenge posed by the spread of antimicrobial-resistant microorganisms. Strains of MRSA are increasing in hospitals and are an important cause of nosocomial infections; in a sample of intensive care units in the United States in 2003, approximately 59.5% of *S. aureus* isolates were resistant to methicillin or oxacillin.²⁸ MRSA strains not only replace methicillin-susceptible strains as a cause of hospital-acquired infections but also actually increase the total burden of nosocomial infections.⁷⁰ Moreover, there are reports that MRSA is becoming a community-acquired pathogen.^{71,72} A population-based surveillance of invasive MRSA infections in the United States performed from July 2004 to December 2005 determined that 85% were healthcare associated and 14% were community associated; 1% could not be classified.⁷² A proactive approach to controlling MRSA at all levels of health care can result in decreased MRSA infection rates.^{73,74}

Strains of GISA, an emerging pathogen first isolated in 1996 in Japan,⁷⁵ exhibit reduced susceptibility to vancomycin and teicoplanin. DNA fingerprinting suggests that these GISA strains evolved from preexisting MRSA strains that infected patients in the months before the GISA infection. Contact precautions are indicated for patients infected or colonized with GISA; infection control guidelines to prevent the spread of GISA are available.⁷⁶

Enterococci

Vancomycin-resistant *Enterococcus* (VRE) accounts for 38.2% of all enterococci in the ICUs participating in the NNIS program.²⁸ Transmission usually occurs through contact with the contaminated hands of a health care worker. The environment is an important reservoir for VRE, but it is not clear whether the environment plays a significant role in transmission.⁷⁷ Risk factors for VRE acquisition include a prolonged hospital stay, liver transplantation, the presence of feeding tubes, dialysis, and exposure to cephalosporins.⁷⁸ Contact precautions are indicated for patients infected or colonized with VRE.^{76,79}

Strategies for preventing and controlling the emergence and spread of antimicrobial-resistant microorganisms have been developed (<http://www.cdc.gov/ncidod/dhqp/pdf/ar/mdroGuideline2006.pdf>). These guidelines include optimizing antimicrobial prophylaxis for surgical procedures; optimizing the choice and duration of empirical therapy; improving antimicrobial prescribing patterns by physicians; monitoring and providing feedback regarding antibiotic resistance; formulating and using practice guidelines for antibiotic usage; developing a system to detect and report trends in antimicrobial resistance; ensuring that caregivers respond rapidly to the detection of antimicrobial resistance in individual patients; incorporating the importance of controlling antimicrobial resistance into the institutional mission and climate; increasing compliance with basic infection control policies and procedures; and developing a plan for identifying, transferring, discharging, and readmitting patients colonized or infected with specific antimicrobial-resistant microorganisms.⁷⁶

Clostridium difficile

C. difficile is recognized as the leading cause of nosocomial infectious diarrhea.⁸⁰ The best-described *C. difficile* virulence factors are toxins A and B.⁸¹ The most important risk factor for *C. difficile*-associated infection (CDI) is previous antibiotic use.⁸⁰ After exposure to *C. difficile*, some patients remain asymptomatic, whereas others experience illnesses ranging from mild diarrhea to fulminant colitis.⁸⁰ The incidence of severe disease leading to death, colectomy, or the need for intensive care is usually no more than 1 to 5%.

In the past few years, CDI outbreaks characterized by increased morbidity and mortality have been reported in the United States, Canada, and Europe. These outbreaks have been attributed to the emergence of a hypervirulent strain of *C. difficile*, which is now referred to as the North American pulsed-field type 1 (NAP1) or PCR ribotype 027.^{82–84} Compared with control strains, the NAP1 strain produces 16-fold greater quantities of toxin A and 23-fold greater quantities of toxin B.⁸⁵

For control of CDI outbreaks, a multifaceted approach is required, including close attention to hand hygiene, use of contact precautions when providing care to CDI patients, environmental disinfection, antibiotic restriction, and rapid laboratory diagnosis.⁸⁶

ENVIRONMENTAL CONTROL

Control of the microbial reservoir of the patient's immediate environment in the hospital is the goal of an infection control program. Environmental control begins with design of the hospital's physical plant. The design must meet the functional standards for patient care and must be integrated into the architecture to provide traffic accessibility and control. Since the 1960s, the practice of centralizing seriously ill patients in intensive care, dialysis, and transplant units has accentuated the need for more careful analysis and planning of space. The primary standards for these special care units and ORs require planning of floor space, physical surfaces, lighting, ventilation, water, and sanitation to facilitate easy cleaning and disinfecting of surfaces, sterilization of instruments, proper food handling, and garbage disposal. These activities should then be governed by practical policies that

are understandable to the staff. Preventive maintenance should be a basic and integral activity of the physical plant department.

Surveillance of the environment by routine culturing of OR floors and walls was discontinued in the late 1970s. Autoclaves and sterilization systems should, however, be continuously monitored with quality control indicators. The results should be documented and records maintained.

Investigations of the physical plant should be reserved for specific outbreaks, depending on the organism and its potential for causing infection. This was demonstrated by an outbreak of sternal wound *Legionella* infections among post-cardiovascular surgery patients after they were exposed to tap water during bathing.⁸⁷ The CDC provides guidelines for infection control issues related to the environment.^{88,89}

Hospital-acquired aspergillosis is caused by another ubiquitous microorganism that is often a contaminant of ambient air during construction. The patients most at risk are usually immunosuppressed (i.e., neutropenic). It is recommended that preventive measures be instituted for these patients when construction is being planned.⁹⁰ The provision of clean (i.e., HEPA-filtered) air in positive pressure-ventilated rooms, with a minimum of 12 air exchanges per hour, is the basic requirement for these patients.⁴⁷

A comprehensive review of environmental infection control in health care facilities is available at the CDC Web site (http://www.cdc.gov/ncidod/dhqp/pdf/guidelines/Enviro_guide_03.pdf). This review contains recommendations for preventing nosocomial infections associated with construction, demolition, and renovation.⁸⁹

EDUCATION

A strategy for routine training of the health care team is necessary at every professional level. The process may vary from institution to institution, but some form of communication should be established for the dissemination of information about the following:

1. Endemic infection rates.
2. Endemic bacterial trends.
3. Updates on infection prevention measures (especially during and after an outbreak).
4. Updates on preventive policies pertaining to hand hygiene, isolation precautions, and other areas of concern.

Although members of the infection control team are the responsible resource persons in the hospital system, each member of the health care team also has a responsibility to help prevent infection in hospitalized patients.

PUBLIC HEALTH AND COMMUNITY HEALTH SERVICE

According to existing public health acts, certain infectious diseases must be reported by law. Differences exist between the reporting systems of one country and those of another, but on the whole, diseases such as tuberculosis, sexually transmitted diseases, and meningococcal meningitis are reported for community follow-up.

Open communication with community hospitals and other health care facilities provides for better management of patients with infections, allowing for notification and planning for additional hospitalization or convalescence as the patient moves to and from the community and hospital.

Benefits of an Infection Control Program

The establishment of an infection control program can greatly benefit a hospital. An infection control program supports patient safety and is a means for continuous quality improvement in the care that is given, in addition to being an accreditation requirement. In Canada and the United States, the need for infection control programs is supported by all governing agents, including the Canadian Council on Hospital Accreditation, JCAHO, the American Hospital Association (AHA), the Canadian Hospital Association, the Association for Practitioners in Infection Control (APIC), the Society of Hospital Epidemiologists of America (SHEA) Joint Commission Task Force, and the Community and Hospital Infection Control Association-Canada (CHICA-Canada).

The effectiveness of infection surveillance and control programs in preventing nosocomial infections in US hospitals was assessed through the SENIC Project.⁹¹ In a representative sample of US general hospitals, infection control programs with a trained infection control physician or microbiologist and at least one infection control nurse per 250 beds were associated with a 32% lower rate of four infections studied (central venous catheter-associated bloodstream infections, ventilator-associated pneumonias, catheter-related urinary tract infections, and SSIs).

Reductions in nosocomial infections have a substantial impact on morbidity, mortality, length of stay, and cost.⁹² In one study, for example, the extra costs associated with treating bloodstream infections in an intensive care setting were estimated to be \$40,000 per survivor.⁹³ Accomplishing a high-quality infection control program requires organization and the dedicated service of all health care employees.

Organization of an Infection Control Program

INFECTION CONTROL COMMITTEE

The chair of the infection control committee should have an ongoing interest in the prevention and control of infections. Members should represent administration, infectious diseases, microbiology, nursing, the OR, central supply, medicine, surgery, pharmacy, and housekeeping. This multidisciplinary group becomes the advocate for the entire hospital. The members work with the infection control service to make decisions in the following areas: (1) assessing the effectiveness and pertinence of infection control policies and protocols in their areas and (2) raising infection control-related concerns.

INFECTION CONTROL SERVICE

Collecting surveillance data on nosocomial infections and taking actions to decrease nosocomial infections are the principal functions of the infection control service. This service usually consists of a trained hospital epidemiologist, infection control practitioners (ICPs), and secretarial and informatics support. The scope of the ICPs' responsibilities has expanded in keeping with the increasing complexity of health care. It is currently recommended that there be 0.8 to 1.0 ICP for every 100 occupied acute care beds.⁹⁴ Training programs to assist with the professional and organizational development of ICPs are available through SHEA (<http://www.shea-online.org>),

APIC (<http://www.apic.org>), and CHICA-Canada (<http://www.chica.org>), and the APIC certification program supports continuous professional improvement. A viable and useful program for surveillance requires a computer database program networked to microbiology, the OR, and

nursing units. Methods for collecting, editing, storing, and sharing data should be based on the CDC's NSHN system, which promotes the use of high-quality indicators for future monitoring and comparison among health care institutions.²⁸

3 PERIOPERATIVE CONSIDERATIONS FOR ANESTHESIA

Steven B. Backman, MDCM, PhD, FRCPC, Richard M. Bondy, MDCM, Alain Deschamps, MD, PhD, Anne Moore, MD, and Thomas Schricker, MD, PhD

Advancements in modern surgical care are complemented by alterations in anesthetic management to provide maximum patient benefit. During the last two decades, anesthesia practice has changed enormously—with the proliferation of airway devices; the routine employment of patient-controlled analgesia; the wider popularity of regional anesthesia, including thoracic epidural anesthesia and peripheral nerve blocks; the development of computer-controlled devices for infusing short-acting drugs; the discovery and use of quickly reversible inhalational drugs, opiates, and muscle relaxants; the availability of online monitoring of central nervous system (CNS) function; and the increased application of transesophageal echocardiography, to name but a few examples. Our aim in this chapter is to offer surgeons a current perspective on perioperative considerations for anesthesia to facilitate dialogue between the surgeon and the anesthesiologist and thereby ensure optimum care for our patients. The primary focus is on the adult patient: the special issues concerning pediatric anesthesia are beyond the scope of our review. In addition, the ensuing discussion is necessarily selective; more comprehensive discussions may be found elsewhere.^{1,2}

Perioperative Patient Management

Preoperative medical evaluation is an essential component of preoperative assessment for anesthesia. Of particular importance to the anesthesiologist is any history of personal or family problems with anesthesia. Information should be sought concerning difficulty with airway management or intubation, drug allergy, delayed awakening, significant postoperative nausea and vomiting (PONV), unexpected hospital or intensive care unit (ICU) admission, and post-dural puncture headache (PDPH). Previous anesthetic records may be requested.

The airway must be carefully examined to identify patients at risk for difficult ventilation or intubation [*see Special Scenarios, Difficult Airway, below*], with particular attention paid to teeth, caps, crowns, dentures, and bridges. Patients must be informed about the risk of trauma associated with intubation and airway management. Anesthetic options [*see Choice of Anesthesia, below*] should be discussed, including the likelihood of postoperative ventilation and admission to the hospital or ICU. When relevant, the possibility of blood product administration should be raised [*see 1:4 Bleeding and Transfusion*], and the patient's acceptance or refusal of transfusion should be carefully documented. Postoperative pain management [*see 1:6 Postoperative Pain*] should be addressed, particularly when a major procedure is planned. The risks

associated with general or regional anesthesia (see below) should be discussed in an informative and reassuring manner; a well-conducted preoperative anesthesia interview plays an important role in alleviating anxiety.

The medications the patient is taking can have a substantial impact on anesthetic management. Generally, patients should continue to take their regular medication up to the time of the operation. It is especially important not to abruptly discontinue medications that may result in withdrawal or rebound phenomena (e.g., beta blockers, alpha antagonists, barbiturates, and opioids). With some medications (e.g., oral hypoglycemics, insulin, and corticosteroids), perioperative dosage adjustments may be necessary [*see 8:10 Endocrine Problems*]. Angiotensin-converting enzyme inhibitors have been associated with intraoperative hypotension and may be withheld at the discretion of the anesthesiologist.³ Drugs that should be discontinued preoperatively include monoamine oxidase inhibitors (MAOIs) and oral anticoagulants [*see Table 1*].

Many surgical patients are taking antiplatelet drugs. Careful consideration should be given to the withdrawal of these agents in the perioperative period [*see Table 1*] because of the possibility that discontinuance may lead to an acute coronary syndrome. Patients with recently placed coronary artery drug-eluting stents (< 1 year) may be at particular risk, so elective surgery should be postponed.⁴ If surgery is necessary, and patients are deemed to be at increased risk for medication-related bleeding during surgery, the longer-acting agents (e.g., aspirin, clopidogrel, and ticlopidine) can be replaced with nonsteroidal antiinflammatory drugs (NSAIDs) that have shorter half-lives. Typically, these shorter-acting drugs are given for 10 days, stopped on the day of surgery, and then restarted 6 hours after operation. Platelet transfusion can be considered if there is a very high potential for significant bleeding.⁵

The increasing use of herbal and alternative medicines has led to significant morbidity and mortality as a consequence of unexpected interactions with traditional drugs. Because many patients fail to mention such agents as part of their medication regimen during the preoperative assessment, it is advisable to question all patients directly about their use. Particular attention should be given to Chinese herbal teas, which include organic compounds and toxic contaminants that may produce renal fibrosis or failure, cholestasis, hepatitis, and thrombocytopenia. Specific recommendations exist for the discontinuance of many of these agents [*see Table 1*].

Prophylactic administration of perioperative beta blockers in patients with or at risk for atherosclerotic disease undergoing noncardiac surgery is controversial and merits specific

Table 1 Recommendations for Preoperative Discontinuance of Drugs and Medicine^{68–81}

Type of Drug	Agent	Pharmacologic Effects	Adverse Effects	Discontinuance Recommendations
MAOIs	Isocarboxazid Phenelzine Pargyline Tranylcypromine Selegiline	Irreversible inhibition of monoamine oxidase with the resultant increase in serotonin, norepinephrine, epinephrine, dopamine, and octamine neurotransmitters	Potential of sympathomimetic amines, possible hypertensive crisis May prolong and intensify effects of other CNS depressants Severe idiopathic hyperpyrexia reaction with meperidine and possibly other narcotics Potential catastrophic interaction with tricyclic antidepressants, characterized by high fever and excessive cerebral excitation and hypertension	Elective surgery: discontinue at least 2 wk in advance; consider potential for suicidal tendency—mental health specialist should be involved Emergency surgery: avoid meperidine; consider regional anesthesia
Oral anticoagulants	Warfarin	Inhibition of vitamin K–dependent clotting factors II, VII, IX, X	Bleeding	Elective surgery: discontinue 5–7 days in advance; replace with heparin if necessary
	Aspirin and NSAIDs Aspirin Fenoprofen Ibuprofen Sodium meclofenamate Tolmetin Indomethacin Ketoprofen Diflunisal Naproxen Sulindac Piroxicam	Inhibition of thromboxane A ₂ 80% of platelets must be inhibited for therapeutic effect Susceptibility to aspirin varies between patients	May increase intraoperative and postoperative bleeding but not transfusion requirement Perioperative hemorrhagic complications increase with increasing half-life of drug	Primary hemostasis normalizes in 48 hr in healthy persons; platelet activity fully recovered in 8–10 days Patients on long-term aspirin therapy for coronary or cerebrovascular pathology should not discontinue drug in perioperative period unless hemorrhagic complications of procedure outweigh risk of acute thrombotic event
Antiplatelet agents	Thienopyridines Ticlopidine Clopidogrel	Inhibition of platelet aggregation Inhibition of platelet ADP-induced amplification	Synergistic antithrombotic effect with aspirin	Discontinue ticlopidine 2 wk in advance; discontinue clopidogrel 7–10 days in advance Patients with coronary artery stents may receive aspirin plus ticlopidine for prolonged period after angioplasty; stopping therapy considerably increases risk of coronary thrombosis; elective surgery should be delayed for 1–3 mo
	Antiglycoprotein agents Eptifibatide Tirofiban Abciximab	Competitive inhibition of GPIIb/IIIa receptors to prevent platelet aggregation Rapid onset of action Short half-lives Often combined with aspirin and/or heparin	Literature (mainly from cardiac surgery) shows increased hemorrhagic risk if surgery undertaken < 12 hr after discontinuance of abciximab Individual variability in recovery time of platelet function	Discontinue at least 12 hr in advance Transfuse platelets only if needed to correct clinically significant bleeding
Herbal medicines	Chaparral	Used as an alternative anticancer agent This herbal agent should be considered as dangerous	Hepatotoxicity	As soon as possible
	Coltsfoot	Used as an antitussive and demulcent agent Considered dangerous	Carcinogenic	As soon as possible
	Comfrey	Used as a general healing agent Considered dangerous	Hepatotoxicity, liver failure	As soon as possible
	Ephedra/ma huang (<i>Ephedra sinica</i>)	Noncatecholamine sympathomimetic agent with α_1 , β_1 , and β_2 activity; both direct and indirect release of endogenous catecholamines	Dose-dependent increase in HR and BP, with potential for serious cardiac and CNS complications Possible adverse drug reactions: MAOIs (life-threatening hypertension, hyperpyrexia, coma), oxytocin (hypertension), digoxin and volatile anesthetics (dysrhythmias), guanethedine (hypertension, tachycardia)	Discontinue at least 24 hr in advance

Table 1 Continued

Type of Drug	Agent	Pharmacologic Effects	Adverse Effects	Discontinuance Recommendations
Herbal medicines	Echinacea (<i>Echinacea purpurea</i>)	Immunostimulatory effect	Hepatotoxicity Allergic potential	Discontinue as far in advance as possible in any patient with hepatic dysfunction or surgery with possible hepatic blood flow compromise
	Feverfew		May increase bleeding especially in patients already on anticlotting medications	At least 7 days
	Garlic (<i>Allium sativum</i>)	Irreversible dose-dependent inhibition of platelet aggregation	Increased bleeding may potentiate other platelet inhibitors	Discontinue at least 7 days in advance
	Germander	Choleretic, antiseptic properties Used in weight control Considered dangerous	Hepatotoxicity	As soon as possible
	Ginkgo (<i>Ginkgo biloba</i>)	Inhibition of platelet-activating factor Modulation of neurotransmitter receptor activity	Increased bleeding May potentiate other platelet inhibitors	Discontinue at least 36 hr in advance
	Ginger (<i>Zingiber officinale</i>)	Potent inhibitor of thromboxane synthase	Increased bleeding May potentiate effects of other anticoagulants	Discontinue at least 36 hr in advance
	Ginseng (<i>Panax ginseng</i>)	Inhibition of platelet aggregation, possibly irreversibly Antioxidant action Antihyperglycemic action “Steroid hormone”-like activity	Prolonged PT and PTT Hypoglycemia Reduced anticoagulation effect of warfarin Possible additive effect with other stimulants, with resultant hypertension and tachycardia	Discontinue at least 7 days in advance
	Goldenseal		May worsen swelling and/or high BP	At least 7 days
	Kava (<i>Piper methysticum</i>)	Dose-dependent potentiation of GABA-inhibitory neurotransmitter with sedative, anxiolytic, and antiepileptic effects	Potential of sedative anesthetics, including barbiturates and benzodiazepines Possible potentiation of ethanol effects	
	Licorice (<i>Glycyrrhiza glabra</i>)		Hypertension Hypokalemia Edema Contraindicated in chronic liver and renal insufficiency	
	Lobelia	Used as an antinausea and mild expectorant Considered dangerous	Respiratory depression, tachycardia, hypotension, hallucinations, coma, death	As soon as possible
	Sassafras	Stimulant, antispasmodic Considered dangerous	Carcinogenic	As soon as possible
	Saw palmetto		May interfere with other hormone therapies	At least 7 days
	St. John's wort (<i>Hypericum perforatum</i>)	Inhibits reuptake of serotonin, norepinephrine, and dopamine by neurons Increases metabolism of some P-450 isoforms	Possible interaction with MAOIs Evidence for reduced activity of cyclosporine, warfarin, calcium channel blockers, lidocaine, midazolam, alfentanil, and NSAIDs	Discontinue on day of surgery; abrupt withdrawal in physically dependent patients may produce benzodiazepine-like withdrawal syndrome
	Valerian (<i>Valeriana officinalis</i>)	Dose-dependent modulation of GABA neurotransmitter and receptor function	Possible potentiation of sedative anesthetics, including barbiturates and benzodiazepines	Discontinue at least 24 hr in advance
	Vitamin E		May increase bleeding, especially in patients taking anticlotting agents May affect thyroid function in otherwise healthy patients In doses greater than 400 IU per day, further increase in BP may be seen in already hypertensive patients	
	Yohimbe	Aphrodisiac, sexual stimulant Considered dangerous	Hypertension, tachycardia, paralysis, death	As soon as possible

ADP = adenosine diphosphate; BP = blood pressure; CNS = central nervous system; GABA = β -aminobutyric acid; GP = glycoprotein; HR = heart rate; MAOIs = monoamine oxidase inhibitors; NSAIDs = nonsteroidal antiinflammatory drugs; PT = prothrombin time; PTT = partial thromboplastin time.

consideration. Although a subgroup of patients may benefit from such treatment with respect to decreased cardiac morbidity, overall, an increased risk of death, stroke, and clinically significant hypotension and bradycardia has been reported.⁶ As such, it is anticipated that guidelines regarding the role for beta blockers in the perioperative setting will continue to evolve.⁷

Inpatient versus Outpatient Surgery

An ever-increasing number of operations are performed on an ambulatory basis [see *ECP:5 Patient Safety in Surgical Care: A Systems Approach*]. Operations considered appropriate for an ambulatory setting are associated with minimal physiologic trespass, low anesthetic complexity, and uncomplicated recovery.^{8,9} The design of the ambulatory facility may impose limitations on the types of operations or patients that can be considered for ambulatory surgery. Such limitations may be secondary to availability of equipment, recovery room nursing expertise and access to consultants, and availability of ICU or hospital beds. Patients who are in class I or class II of the American Society of Anesthesiologists (ASA) physical status scale are ideally suited for ambulatory surgery; however, a subset of ASA class III patients may be at increased risk for prolonged recovery and hospital admission [see *Table 2*].

Premedication to produce anxiolysis, sedation, analgesia, amnesia, and reduction in PONV and aspiration may be considered for patients undergoing outpatient procedures, as it may for those undergoing inpatient procedures. Such premedication should not delay discharge. Fasting guidelines [see *Table 3*] and intraoperative monitoring standards for ambulatory surgery are identical to those for inpatient procedures [see *Patient Monitoring, below*].

A number of currently used anesthetics (e.g., propofol, sevoflurane, desflurane), narcotics (e.g., alfentanil, fentanyl, sufentanil, and remifentanyl), and muscle relaxants (e.g., succinylcholine, atracurium, mivacurium, and rocuronium) demonstrate rapid recovery profiles. Nitrous oxide also has desirable pharmacokinetic properties, but it may be associated with increased PONV. Titration of anesthetics to indices of CNS activity (e.g., the bispectral index) may result in decreased drug dosages, faster recovery from anesthesia, and fewer complications.^{10,11} Multimodal analgesia (involving the use of local anesthetics, ketamine, α_2 -adrenergic agonists, beta blockers, acetaminophen, or NSAIDs) may reduce

Table 3 Fasting Recommendations* to Reduce Risk of Pulmonary Aspiration⁸³

Ingested Material	Minimum Fasting Period [†] (hr)
Clear liquids [‡]	2
Breast milk	4
Infant formula	6
Nonhuman milk [§]	6
Light meal	8

*These recommendations apply to healthy patients undergoing elective procedures; they are not intended for women in labor. Following the guidelines does not guarantee complete gastric emptying.

[†]These fasting periods apply to all ages.

[‡]Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.

[§]Because nonhuman milk is similar to solids in gastric emptying time, the amount ingested must be considered in determining the appropriate fasting period.

^{||}A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Both the amount and type of foods ingested must be considered in determining the appropriate fasting period.

intraoperative and postoperative opioid requirements and accelerate patient discharge. Use of a laryngeal mask airway rather than an endotracheal tube is ideal in the outpatient setting because lower doses of induction agent are required to blunt the hypertension and tachycardia associated with its insertion; in addition, it is associated with a decreased incidence of sore throat and does not require muscle paralysis for insertion. On the other hand, a laryngeal mask airway may not protect against aspiration.^{12,13}

The benefits of regional anesthesia [see *Regional Anesthesia Techniques, below*] may include decreases in the incidence of aspiration, nausea, dizziness, and disorientation. Spinal and epidural anesthesia may be associated with headache (dural puncture) and backache. Compared with spinal anesthesia, epidural anesthesia takes more time to perform, has a slower onset of action, and may not produce as profound a block; however, the duration of an epidural block can readily be extended intraoperatively or postoperatively if necessary. Care should be exercised in choosing a local anesthetic for neuraxial blockade: spinal lidocaine may be associated with a transient radicular irritation, and bupivacaine may be associated with prolonged motor block; narcotics may produce pruritus, urinary retention, nausea and vomiting, and respiratory depression. Various dosing regimens, including minidose spinal techniques, have been proposed as means of minimizing these side effects.¹⁴⁻¹⁷

Monitored anesthesia care [see *Choice of Anesthesia, below*] achieves minimal CNS depression, so the airway and spontaneous ventilation are maintained and the patient is able to respond to verbal commands. Meticulous attention to monitoring is required to guard against airway obstruction, arterial desaturation, and pulmonary aspiration.

In the recovery room, the anesthetic plan is continued until discharge. Shorter-acting narcotics and NSAIDs are administered for pain relief, and any of several agents may be given for control of nausea and vomiting. Criteria for discharge from the recovery room have been established [see *Table 4*]. Recovery of normal muscle strength and sensation (including proprioception of the lower extremity, autonomic function, and ability to void) should be demonstrated after spinal or epidural anesthesia. Delays in discharge are usually the result

Table 2 Association between Preexisting Medical Conditions and Adverse Outcomes⁸²

Medical Condition	Associated Adverse Outcome
Congestive heart failure	12% prolongation of postoperative stay
Hypertension	Twofold increase in risk of intraoperative cardiovascular events
Asthma	Fivefold increase in risk of postoperative respiratory events
Smoking	Fourfold increase in risk of postoperative respiratory events
Obesity	Fourfold increase in risk of intraoperative and postoperative respiratory events
Reflux	Eightfold increase in risk of intubation-related adverse events

Table 4 Postanesthetic Discharge Scoring System (PADSS)⁸⁴

Category	Score*	Explanation
Vital signs	2	Within 20% of preoperative value
	1	Within 20 to 40% of preoperative value
	0	Within 40% of preoperative value
Activity, mental status	2	Oriented and steady gait
	1	Oriented or steady gait
	0	Neither
Pain, nausea, vomiting	2	Minimal
	1	Moderate
	0	Severe
Surgical bleeding	2	Minimal
	1	Moderate
	0	Severe
Intake/output	2	Oral fluid intake and voiding
	1	Oral fluid intake or voiding
	0	Neither

*Total possible score is 10; patients scoring ≥ 9 are considered fit for discharge home.

of pain, PONV, hypotension, dizziness, unsteady gait, or lack of an escort.¹⁸

Elective versus Emergency Surgery

Surgical procedures performed on an emergency basis may range from relatively low priority (e.g., a previously cancelled case that was originally elective) to highly urgent (e.g., a case of impending airway obstruction). For trauma, specific evaluation and resuscitation sequences have been established to facilitate patient management [see 7:1 *Initial Management of Life-Threatening Trauma*]. The urgency of the situation dictates how much time can be allotted to preoperative patient assessment and optimization. When it is not possible to communicate with the patient, information obtained from family members and paramedics may be crucial. Information should be sought concerning allergies, current medications, significant past medical illnesses, nihil per os (NPO) status, personal or family problems with anesthesia, and recent ingestion of alcohol or drugs. Any factor that may complicate airway management should be noted (e.g., trauma to the face or the neck, a beard, a short and thick neck, obesity, or a full stomach). When appropriate, blood samples should be obtained as soon as possible for typing and cross-matching, as well as routine blood chemistry, complete blood count, and toxin screen. Arrangements for postoperative ICU monitoring, if appropriate, should be instituted early.

Clear communication must be established between the surgical team and anesthesia personnel so that an appropriate anesthetic management plan can be formulated and any specialized equipment required can be mobilized in the operating room (OR). The induction of anesthesia may coincide with resuscitation. Accordingly, the surgical team must be immediately available to help with difficult intravenous (IV) access, emergency tracheostomy, and cardiopulmonary resuscitation. Patients in shock may not tolerate standard anesthetics, which characteristically blunt sympathetic outflow. The anesthetic dose must be judiciously titrated, and

definitive surgical treatment must not be unduly delayed by attempts to “get a line.”

Choice of Anesthesia

Anesthesia may be classified into three broad categories: (1) general anesthesia, (2) regional anesthesia, and (3) monitored anesthesia care. General anesthesia can be defined as a state of insensibility characterized by loss of consciousness, amnesia, analgesia, and muscle relaxation. This state may be achieved either with a single anesthetic or, in a more balanced fashion, with a combination of several drugs that specifically induce hypnosis, analgesia, amnesia, and paralysis.

There is, at present, no consensus as to which general anesthetic regimen best preserves organ function. General anesthesia is employed when contraindications to regional anesthesia are present or when regional anesthesia or monitored anesthesia care fails to provide adequate intraoperative analgesia. In addition, a few situations specifically mandate general anesthesia and controlled ventilation: the need for abdominal muscle paralysis, lung isolation, and hyperventilation; the presence of serious cardiorespiratory instability; and the lack of sufficient time to perform regional anesthesia. Alternatives to general anesthesia should be considered for patients who are susceptible to malignant hyperthermia (MH), for those in whom intubation is likely to prove difficult or the risk of aspiration is high, and for those with pulmonary compromise that may worsen after intubation and positive pressure ventilation.

Regional anesthesia is achieved by interfering with afferent or efferent neural signaling at the level either of the spinal cord (neuraxial blockade) or of the peripheral nerves. Neuraxial anesthesia (i.e., epidural or spinal administration of local anesthetics) is commonly employed as the sole anesthetic technique for procedures involving the lower abdomen and the lower extremities; it also provides effective pain relief after intraperitoneal and intrathoracic procedures. Combining regional and general anesthesia has become increasingly popular.¹⁹ Currently, some physicians are using neuraxial blockade as the sole anesthetic technique for procedures such as thoracotomy and coronary artery bypass grafting, which are traditionally thought to require general anesthesia and endotracheal intubation.²⁰

Neuraxial blockade has several advantages over general anesthesia, including better dynamic pain control, shorter duration of paralytic ileus, reduced risk of pulmonary complications, and decreased transfusion requirements; it is also associated with a decreased incidence of renal failure and myocardial infarction [see 1:6 *Postoperative Pain*].^{21–24} Contrary to conventional thinking, however, the type of anesthesia used (general or neuraxial) is not an independent risk factor for long-term cognitive dysfunction.²⁵ Neuraxial blockade is an essential component of multimodal rehabilitation programs aimed at optimization of perioperative care and acceleration of recovery [see ECP:3 *Perioperative Considerations for Anesthesia*].^{26,27}

For short, superficial procedures, a variety of peripheral nerve blocks may be considered.²⁸ With procedures on the upper or lower extremity, an IV regional (Bier) block with diluted lidocaine may be useful. Anesthesia of the upper extremity and shoulder may be achieved with the brachial plexus block. Anesthesia of the lower extremity may be

achieved by blocking the femoral, obturator, and lateral femoral cutaneous nerves (knee surgery) or the ankle and popliteal sciatic nerves (foot surgery). Anesthesia of the thorax may be achieved with intercostal or intrapleural nerve blocks. Anesthesia of the abdomen may be achieved with celiac plexus and paravertebral blocks. Anesthesia of the head and neck may be achieved by blocking the trigeminal, supraorbital, supratrochlear, infraorbital, and mental nerves and the cervical plexus. Local infiltration of the operative site may provide intraoperative and postoperative analgesia.

Unlike the data on neuraxial blockade, the data on peripheral nerve blockade neither support nor discourage its use as a substitute for general anesthesia. Generally, however, we favor regional techniques when appropriate: such approaches maintain consciousness and spontaneous breathing while causing only minimal depression of the CNS and the cardiorespiratory systems, and they yield improved pain control in the immediate postoperative period.

Monitored anesthesia care involves the use of IV drugs to reduce anxiety, provide analgesia, and alleviate the discomfort of immobilization. This approach may be combined with local infiltration analgesia provided by the surgeon.²⁹ Monitored anesthesia care requires monitoring of vital signs and the presence of an anesthesiologist who is prepared to convert to general anesthesia if necessary. Its benefits are substantially similar to those of regional anesthesia. These benefits are lost when attempts are made to overcome surgical pain with excessive doses of sedatives and analgesics.

Patient Monitoring

Patient monitoring is central to the practice of anesthesia. A trained, experienced physician is the only truly indispensable monitor; mechanical and electronic monitors, although useful, are, at most, aids to vigilance. Wherever anesthesia is administered, the proper equipment for pulse oximetry, blood pressure measurement, electrocardiography, and capnography should be available. At each anesthesia workstation, equipment for measuring temperature, a peripheral nerve stimulator, a stethoscope, and appropriate lighting must be immediately available. A spirometer must be available without undue delay.

Additional monitoring may be indicated, depending on the patient's health, the type of procedure to be performed, and the characteristics of the practice setting. Cardiovascular monitoring, including measurement of systemic arterial, central venous, pulmonary arterial, and wedge pressures; cardiac output; and continuous arterial and mixed venous oximetry, is covered in detail elsewhere [see 8:3 *Shock*]. Additional information about the cardiovascular system may be obtained by transesophageal echocardiography.³⁰ Practice guidelines for this technique have been developed.³¹ It may be particularly useful in patients who are undergoing valve repair or who have persistent severe hypotension of unknown etiology.

The effects of anesthesia on the CNS may be assessed by monitoring electroencephalographic (EEG) activity that is either spontaneous (raw or processed) or evoked (e.g., somatosensory, auditory, or visual). Commercially available devices that employ spectral analysis of spontaneous EEG activity (e.g., bispectral index) are relatively easy to use and

are advocated by some as measures of hypnosis to guide the administration of anesthetics.^{32,33} However, their effectiveness in preventing intraoperative awareness remains controversial, particularly when anesthesia is maintained by inhalational drugs.³⁴ CNS function may also be assessed by measurement of cerebral blood flow, using transcranial Doppler, jugular bulb venous oxygen saturation, and cerebral oximetry monitoring techniques. Although there is growing clinical experience with these noninvasive intraoperative neurologic monitors, randomized, prospective, and adequately powered studies to support and guide their use are currently lacking.

General Anesthesia Techniques

An ever-expanding armamentarium of drugs is available for premedication and for induction and maintenance of anesthesia. Selection of one agent over another is influenced by the patient's baseline condition, procedure, local standard of practice, and predicted duration of hospitalization.

PREMEDICATION

Preoperative medications are given primarily to decrease anxiety, to reduce the incidence of nausea and vomiting, and to prevent aspiration. Other benefits include sedation, amnesia, analgesia, drying of oral secretions, and blunting of undesirable autonomic reflexes.

Sedatives and Analgesics

Benzodiazepines produce anxiolysis, sedation, hypnosis, amnesia, and muscle relaxation; they do not produce analgesia. They may be classified as short acting (midazolam), intermediate acting (lorazepam), or long acting (diazepam). Adverse effects [see Table 5] may be marked in debilitated patients. Their central effects may be antagonized with flumazenil.

Muscarinic antagonists (e.g., scopolamine and atropine) were commonly administered at one time; this practice is not as popular today. They produce, to varying degrees, sedation, amnesia, lowered anesthetic requirements, diminished nausea and vomiting, reduced oral secretions, and decreased gastric hydrogen ion secretion. They blunt the cardiac parasympathetic reflex responses that may occur during certain procedures (e.g., ocular surgery, traction on the mesentery, and manipulation of the carotid body). Adverse effects include

Table 5 Benzodiazepines: Doses and Duration of Action⁸⁵

Benzodiazepine	Dose (for Sedation)	Elimination Half-Life	Comments
Midazolam	0.5–1.0 mg, repeated	1.7–2.6 hr	Respiratory depression, excessive sedation, hypotension, bradycardia, anticonvulsant activity (withdrawal)
Lorazepam	0.25 mg, repeated	11–22 hr	See midazolam Venous thrombosis
Diazepam	2.0 mg, repeated	20–50 hr	See midazolam and lorazepam

tachycardia, heat intolerance, inhibition of gastrointestinal (GI) motility and micturition, and mydriasis.

Opioids are used when analgesia, in addition to sedation and anxiolysis, is required. With morphine and meperidine, the time of onset of action and the peak effect are unpredictable. Synthetic opioids (e.g., fentanyl) have a more rapid onset and a predictable time course, which make them more suitable for premedication immediately before surgery. Adverse effects [see Table 6] can be reversed with full (naloxone) or partial (nalbuphine) antagonists.

The α_2 -adrenergic agonists clonidine and dexmedetomidine are sympatholytic drugs that also exert sedative, anxiolytic, and analgesic effects. They reduce intraoperative anesthetic requirements, thus allowing faster recovery, and attenuate sympathetic activation secondary to intubation and surgery, thus improving intraoperative hemodynamic stability. Major drawbacks are hypotension and bradycardia; rebound hypertensive crises may be precipitated by their discontinuance.^{35,36}

Prevention of Aspiration

Aspiration of gastric contents is an extremely serious complication that is associated with significant morbidity and mortality. Fasting helps reduce the risk of this complication [see Table 3]. When the likelihood of aspiration is high,

pharmacologic treatment may be helpful [see Table 7]. H_2 receptor antagonists (e.g., cimetidine, ranitidine, and famotidine) and proton pump inhibitors (e.g., omeprazole) reduce gastric acid secretion, thereby raising gastric pH without affecting gastric volume or emptying time. Nonparticulate antacids (e.g., sodium citrate) neutralize the acidity of gastric contents. Metoclopramide promotes gastric emptying (by stimulating propulsive GI motility) and decreases reflux (by increasing the tone of the esophagogastric sphincter); it may also possess antiemetic properties.

In all patients at risk for aspiration who require general anesthesia, a rapid sequence induction is traditionally considered a standard of practice, although this has been recently questioned.³⁷ A rapid sequence induction is achieved through adequate preoxygenation, administration of drugs to produce rapid loss of consciousness and paralysis, and exertion of pressure on the cricoid cartilage (the Sellick maneuver) as loss of consciousness occurs to occlude the esophagus and so limit reflux of gastric contents into the pharynx. An alternative is the so-called modified rapid sequence induction, which permits gentle mask ventilation during the application of cricoid pressure (thereby potentially reducing or abolishing insufflation of gas into the stomach). The advantages of the modified approach are that there is less risk of hypoxia and more time to treat cardiovascular responses to induction

Table 6 Opioids: Doses and Duration of Action⁸⁶

Agent Induction	Relative Analgesic Potency Maintenance	Dose		Time to Peak Effect	Duration of Action	Comments
		Induction or Loading	Maintenance			
Morphine	1	1 mg/kg For perioperative analgesia: 0.1 mg/kg IV, IM	0.05–0.2 mg/kg/hr	5–20 min	2–7 hr	Respiratory depression, nausea, vomiting, pruritus, constipation, urinary retention, biliary spasm, neuroexcitation ± seizure, tolerance Cough suppression, relief of dyspnea-induced anxiety (common to all opioids) Histamine release, orthostatic hypotension, prolonged emergence
Meperidine	0.1	For perioperative analgesia: 0.5–1.5 mg/kg IV, IM, SC	NA	2 hr (oral); 1 hr (SC, IM)	2–4 hr	See morphine Orthostatic hypotension, myocardial depression, dry mouth, mild tachycardia, mydriasis, histamine release Attenuates shivering; to be avoided with MAOIs Local anesthetic-like effect
Remifentanyl	250–300	1 µg/kg	0.25–0.4 µg/kg/min	3–5 min	5–10 min	See morphine Awareness, bradycardia, muscle rigidity Ideal for infusion; fast recovery, no postoperative analgesia
Alfentanil	7.5–25	50–300 µg/kg	1.25–8.0 µg/kg/min	1–2 min	10–15 min	See morphine Awareness, bradycardia, muscle rigidity
Fentanyl	75–125	5–30 µg/kg	0.25–0.5 µg/kg/min	5–15 min	30–60 min	See morphine and alfentanil
Sufentanil	525–625	2–20 µg/kg	0.05–0.1 µg/kg/min	3–5 min	20–45 min	See morphine and alfentanil Ideal for prolonged infusion

IM = intramuscular; IV = intravenous; MAOI = monoamine oxidase inhibitor; NA = not applicable; SC = subcutaneous.

Table 7 Pharmacologic Prevention of Aspiration^{87,88}

Agent	Dose	Timing of Administration before Operation	Comments
H ₂ receptor antagonists Cimetidine Ranitidine Famotidine	300 mg, PO 50 mg IV 20 mg IV	1–3 hr	Hypotension, bradycardia, heart block, increased airway resistance, CNS dysfunction, reduced hepatic metabolism of certain drugs Bradycardia Rare CNS dysfunction
Sodium citrate	30 mL PO	20–30 min	Increased gastric fluid volume
Omeprazole	40 mg IV	40 min	Possible alteration of GI drug absorption, hepatic metabolism
Metoclopramide	10 mg IV	15–30 min	Extrapyramidal reactions, agitation, restlessness (large doses); to be avoided with MAOIs, pheochromocytoma, bowel obstruction

CNS = central nervous system; GI = gastrointestinal; IV = intravenous; MAOI = monoamine oxidase inhibitor; PO = oral.

agents before intubation. Regardless of which technique is used, consideration should be given to emptying the stomach via an orogastric or nasogastric tube before induction.

INDUCTION

Induction of general anesthesia is achieved by administering drugs to produce unconsciousness. It is one of the most crucial and potentially dangerous moments for the patient during general anesthesia because of the precipitous depression of the cardiorespiratory systems and airway protective mechanisms. Various agents can be used for this purpose; the choice depends on the patient's baseline medical condition and fasting status, the state of the airway, the surgical procedure, and the expected length of the hospital stay. The agents most commonly employed for induction are propofol, sodium thiopental, ketamine, and etomidate [see Table 8]. The opioids alfentanil, fentanyl, sufentanil, and remifentanyl may also be used for this purpose; they are associated with a very stable hemodynamic profile during induction and surgery but only invariably produce unconsciousness [see Table 6].

Volatile agents [see Table 9] may be employed for induction of general anesthesia when maintenance of spontaneous ventilation is of paramount importance (e.g., with a difficult airway) or when bronchodilation is required (e.g., with severe

hyperreactive airway disease). Inhalation induction is also popular for ambulatory surgery when paralysis is not required. Sevoflurane is well suited for this application because it is not irritating on inhalation, as are most other volatile agents, and it produces rapid loss of consciousness. Sevoflurane has mostly replaced halothane as the agent of choice for inhalation induction because it is less likely to cause dysrhythmias and is not hepatotoxic.

MAINTENANCE

Balanced general anesthesia is produced with a variety of drugs to maintain unconsciousness, prevent recall, and provide analgesia. Various combinations of volatile and IV agents may be employed to achieve these goals. The volatile agents isoflurane, desflurane, and sevoflurane are commonly used for maintenance [see Table 9]. Nitrous oxide is a strong analgesic and a weak anesthetic agent that possesses favorable pharmacokinetic properties (fast onset, fast offset). Because of its relatively high blood:gas partition coefficient compared with nitrogen, nitrous oxide rapidly diffuses into and expands air-filled cavities. Thus, it should be avoided in situations in which expansion of such cavities is undesirable (e.g., pneumothorax, air embolism, bowel obstruction, and middle ear surgery). It cannot be used as the sole anesthetic agent unless

Table 8 Induction Agents: Doses and Duration of Action⁸⁸

Agent	Induction Dose (mg/kg)	Time to Peak Effect (s)	Duration of Action (min)	Comments
Propofol	1.0–2.5	90–100	5–10	Hypotension, apnea, antiemetic (low dose), sexual fantasies and hallucinations, convulsions ± seizures (rare), pain on injection, thrombophlebitis
Thiopental	2.5–4.5	60	5–8	Hypotension, apnea, emergence delirium, prolonged somnolence, anaphylactoid reaction, injection pain, hyperalgesia Anticonvulsant effect Contraindicated with porphyria
Ketamine	0.5–2	30	10–15	Analgesia; increased BP, HR, CO; lacrimation and salivation; bronchial dilatation; elevated ICP Dreaming, illusions, excitement Preservation of respiration (apnea possible with high doses)
Etomidate	0.2–0.6	60	4–10	Minor effects on BP, HR, CO Adrenocortical suppression, injection pain and thrombophlebitis, myoclonus, nausea and vomiting

BP = blood pressure; CO = cardiac output; HR = heart rate; ICP = intracranial pressure.

Table 9 Volatile Drugs^{89,90}

Agent	Oil/Gas Coefficient*	MAC† (atm)	Blood/Gas Coefficient‡	Rank Order (FA/FI)§
Halothane	224	0.0074	2.5	6
Enflurane	96.5	0.0168	1.8	5
Isoflurane	90.8	0.0115	1.4	4
Desflurane	18.7	0.060	0.45	2
Sevoflurane	47.2	0.0236	0.65	3
Nitrous oxide	1.4	1.04	0.47	1

FA/FI = alveolar concentration of gas/inspired concentration; MAC = minimum alveolar concentration to abolish purposeful movement in response to noxious stimulation in 50% of patients.

*Lipid solubility correlates closely with anesthetic potency (Meyer-Overton rule).

†Correlates closely with lipid solubility.

‡Relative affinity of an anesthetic for blood compared to gas at equilibrium. The larger the coefficient, the greater the affinity of the drug for blood and hence the greater the quantity of drug contained in the blood.

§Rise in alveolar anesthetic concentration toward the inspired concentration is most rapid with the least soluble drugs and slowest with the most soluble.

it is administered in a hyperbaric chamber; it is usually administered with at least 30% oxygen to prevent hypoxia. Nitrous oxide is commonly used in combination with other volatile agents. Potent volatile agents can trigger malignant hyperthermia in susceptible patients.

The IV drugs currently used to maintain general anesthesia, whether partially or entirely, feature a short, context-sensitive elimination half-life; thus, pharmacologically significant drug accumulation during prolonged infusion is avoided. Such agents (including propofol, midazolam, sufentanil, and remifentanyl) are typically administered via computer-controlled infusion pumps that use population-based pharmacokinetic data to establish stable plasma (and CNS effector site) concentrations. Because of the extremely rapid

hydrolysis of remifentanyl, its administration may be labor intensive, necessitating frequent administration of boluses and constant vigilance. Its short half-life also limits its usefulness as an analgesic in the postoperative period and may even contribute to acute opioid intolerance. To help circumvent these problems, various dosing regimens have been proposed in which the patient is switched from remifentanyl to a longer-acting narcotic.

NEUROMUSCULAR BLOCKADE

The reversible paralysis produced by neuromuscular blockade improves conditions for endotracheal intubation and facilitates surgery. Neuromuscular blocking agents are classified as either depolarizing (succinylcholine) or nondepolarizing (pancuronium, rocuronium, vecuronium, atracurium, cisatracurium, and mivacurium) and may be further differentiated on the basis of chemical structure and duration of action [see Table 10]. The blocking effect of nondepolarizing muscle relaxants is enhanced by volatile drugs, hypothermia, acidosis, certain antibiotics, magnesium sulfate, and local anesthetics and is reduced by phenytoin and carbamazepine. Patients with weakness secondary to neuromuscular disorders (e.g., myasthenia gravis and Eaton-Lambert syndrome) may be particularly sensitive to nondepolarizing muscle relaxants.

EMERGENCE

General anesthesia is terminated by cessation of drug administration, reversal of muscle paralysis, and extubation (or removal of an upper airway device). During this potentially dangerous period, close scrutiny of the patient is essential, and all OR personnel must coordinate their efforts to help ensure a smooth and safe emergence from general anesthesia. In this phase, patients may demonstrate hemodynamic instability, retching and vomiting, respiratory compromise (including laryngospasm), and, occasionally, uncooperative or aggressive behavior.³⁸

Table 10 Neuromuscular Blocking Agents: Doses and Duration of Action⁹¹

Agent	Dose (mg/kg)	Duration of Action (min)	Metabolism	Elimination	Comments
Succinylcholine chloride	0.7–2.5	5–10	Plasma cholinesterase	Renal < 2%, hepatic 0%	Fasciculations, elevation of serum potassium, increased ICP, bradycardia, MH trigger; prolonged effect in presence of atypical pseudocholinesterase
Pancuronium	0.04–0.1	60–120	Hepatic 10–20%	Renal 85%, hepatic 15%	Muscarinic antagonist (vagolytic), prolonged paralysis (long-term use)
Rocuronium	0.6–1.2	35–75	None	Renal < 10%, hepatic > 70%	Minimal histamine release
Vecuronium	0.08–0.1	45–90	Hepatic 30–40%	Renal 40%, hepatic 60%	Prolonged paralysis (long-term use)
Atracurium	0.3–0.5	30–45	Hoffman elimination, nonspecific ester hydrolysis	Renal 10–40%, hepatic 0%	Histamine release; laudanosine metabolite (a CNS stimulant)
Cisatracurium	0.15–0.2	40–75	Hoffman elimination	Renal 16%, hepatic 0%	Negligible histamine release; laudanosine metabolite
Mivacurium	0.15–0.2	15–20	Plasma cholinesterase	Renal < 5%, hepatic 0%	Histamine release; prolonged effect in presence of atypical pseudocholinesterase

CNS = central nervous system; ICP = intracranial pressure; MH = malignant hyperthermia.

Reversal of neuromuscular blockade is achieved by administering anticholinesterases such as neostigmine or edrophonium. These drugs should be given in conjunction with a muscarinic antagonist (atropine or glycopyrrolate) to block their unwanted parasympathomimetic side effects. Neostigmine is more potent than edrophonium in reversing profound neuromuscular blockade. It is imperative that paralysis be sufficiently reversed before extubation to ensure that spontaneous respiration is adequate and that the airway can be protected. Reversal can be clinically verified by confirming the patient's ability to lift the head for 5 seconds. Reversal can also be assessed by muscle contraction response to electrical nerve stimulation.

Causes of failure to emerge from anesthesia include residual neuromuscular blockade, a benzodiazepine or opioid overdose, the central anticholinergic syndrome, an intraoperative cerebrovascular accident, preexisting pathophysiologic conditions (e.g., CNS disorders, hepatic insufficiency, and drug or alcohol ingestion), electrolyte abnormalities, acidosis, hypercarbia, hypoxia, hypothermia, and hypothyroidism. As noted, the effects of narcotics and benzodiazepines can be reversed with naloxone and flumazenil, respectively. Physostigmine may be given to reverse the reduction in consciousness level produced by general anesthetics. Electrolyte, glucose, blood urea nitrogen, and creatinine levels should be measured; liver and thyroid function tests should be performed; and arterial blood gas values should be obtained. Patients should be normothermic. Unexplained failure to emerge from general anesthesia warrants immediate consultation with a neurologist.

Risk and General Anesthesia

Determining the risk(s) attributed solely to anesthesia is difficult because of the confounding variables of patient characteristics, concurrent medications, and the surgical procedure itself, including context (e.g., elective versus emergency). Prospective, unbiased studies sufficiently powered to reveal the frequency of rare events are lacking, and reliance on self-reporting of negative outcomes likely results in an underestimation of risk. Given these limitations, attempts have been made to define the risks associated with anesthesia, based on extensive and critical literature reviews [see Table 11].³⁹ Perioperative mortality associated with anesthesia increases with age, ASA status, and emergency procedures. Factors contributing to anesthesia-related mortality include inadequate assessment, preparation and resuscitation, inappropriate anesthetic technique, inadequate perioperative monitoring, lack of supervision, and poor postoperative care. Morbidity ranges from major permanent disability to relatively minor events without long-term consequence. Peripheral nerve injury, although rare, may have serious disability. The etiology includes direct injury from needles, instruments, suturing, injection of toxic substances, and thermal insults. Less obvious but more frequent events involve mechanical factors such as nerve compression or stretch. Ischemia associated with a low cardiac output state is often implicated.⁴⁰ Great caution must be used during patient positioning, with careful attention to proper padding. Loss of vision is a rare but catastrophic event that may be associated with compression of the eye by a facemask or by padding of

the headrest used in the prone position.⁴¹ The relationship between postoperative cognitive dysfunction (POCD) and anesthesia per se remains unclear and may occur in patients who receive general (intravenous or inhalational) or regional anesthesia. POCD does not seem to be associated with intraoperative hypoxemia, hypotension, or acid-base disturbances. Certain procedures, such as cardiac and orthopedic surgery, have been associated with this disorder, and a common etiology (air, particulate, or fat microemboli) is implicated. There is a growing appreciation that even with other types of surgery, POCD can occur, with elderly patients (more than 60 years) being at particular risk during the first week after the procedure. Presently, there is little evidence that POCD persists longer than 6 months.⁴²

Regional Anesthesia Techniques

Neuraxial (central) anesthesia techniques involve continuous or intermittent injection of drugs into the epidural or intrathecal space to produce sensory analgesia, motor blockade, and inhibition of sympathetic outflow. Peripheral nerve blockade involves inhibition of conduction in fibers of a single peripheral nerve or plexus (cervical, brachial, or lumbar) in the periphery. Intravenous regional anesthesia involves IV administration of a local anesthetic into a tourniquet-occluded extremity. Perioperative pain control may be facilitated by administering local anesthetics, either infiltrated into the wound or sprayed into the wound cavity. Procedures performed solely under infiltration may be associated with patient dissatisfaction caused by intraoperative anxiety and pain.^{43,44}

CONTRAINDICATIONS

Strong contraindications to regional (particularly neuraxial) anesthesia include patient refusal or inability to cooperate during the procedure, elevated intracranial pressure, anticoagulation, vascular malformation or infection at the needle insertion site, severe hemodynamic instability, and sepsis. Preexisting neurologic disease is a relative contraindication.

ANTICOAGULATION AND BLEEDING RISK

Although hemorrhagic complications can occur after any regional technique, bleeding associated with neuraxial blockade is the most serious possibility because of its devastating consequences. Spinal hematoma may occur as a result of vascular trauma from placement of a needle or catheter into the subarachnoid or epidural space. Spinal hematoma may also occur spontaneously, even in the absence of antiplatelet or anticoagulant therapy. The actual incidence of spinal cord injury resulting from hemorrhagic complications is unknown; the reported incidence is estimated to be less than 1 in 150,000 for epidural anesthesia and 1 in 200,000 for spinal anesthesia [see Table 12].⁴⁵ With such low incidences, it is difficult to determine whether any increased risk can be attributed to anticoagulant use [see Table 13] without data from millions of patients, which are not currently available. Much of our clinical practice is based on small surveys and expert opinion.

Antiplatelet Agents

There is no universally accepted test that can guide antiplatelet therapy. Antiplatelet agents can be divided into

Table 11 Predicted Incidence of Complications of Anesthesia³⁹

Mortality and Morbidity	Approximate Incidence	Rate per 10,000 Population	Remarks
Total perioperative deaths (within 30 days)	1:200 (elective surgery) 1:40 (emergency surgery) × 2 (60–79 yr) × 5 (80–89 yr) × 7 (> 90 yr)	50 250	
Death related to anesthesia	1:50,000 (anesthesia related) 1:100,000 (ASA physical status I and II)	0.2 0.1	
Cardiac arrest	1:10,000–1:20,000 (general anesthesia) 1:3,000 (local anesthesia) 1:1,500 (spinal: 25% fatal)	0.5–1.0 3 7	Mortality ≈ 1:15,000–1:150,000
Myocardial reinfarction	1:20 (0–3 mo after myocardial infarction) 1:40 (4–6 mo after myocardial infarction)	500 250	
Respiratory complications			
Aspiration during general anesthesia	1:3,000 1:60,000 (death)	3 0.16	× 4 in emergencies × 3 in obstetrics

Subclavian vein cannulation	1:200	50	

ASA = American Society of Anesthesiologists.

four major classes: (1) aspirin and related cyclooxygenase inhibitors (NSAIDs); (2) ticlopidine and selective adenosine diphosphate antagonists; (3) direct thrombin inhibitors (e.g., hirudin); and (4) glycoprotein IIb/IIIa inhibitors. Only with aspirin is there sufficient experience to suggest that it does not increase the risk of spinal hematoma when given at clinical dosages.⁴⁶ Caution should, however, be exercised when aspirin is used in conjunction with other anticoagulants.⁴⁷

Oral Anticoagulants

Therapeutic anticoagulation with warfarin is a contraindication to regional anesthesia.⁴⁸ If regional anesthesia is planned, oral warfarin can be replaced with IV heparin (see below).

Heparin

There does not seem to be an increased risk of spinal bleeding in patients receiving subcutaneous low-dose (5,000 U) unfractionated heparin [see 6:6 *Venous Thromboembolism*] if the interval between administration of the drug and initiation of the procedure is greater than 4 hours.⁴⁹ Higher doses, however, are associated with increased risk. If neuraxial anesthesia or epidural catheter removal is planned, heparin infusion must be discontinued for at least 6 hours, and the partial thromboplastin time should be measured. Recommendations for standard heparin cannot be extrapolated to low-molecular-weight heparin (LMWH), because the biologic actions of LMWH are different and the effects cannot be monitored by conventional coagulation measurements. After the release of LMWH for general use in the United States in 1993, more than 40 spinal hematomas were reported

during a 5-year period. LMWH should be stopped at least 24 hours before regional blockade, and the first postoperative dose should be given no sooner than 24 hours afterward.⁴⁷

COMPLICATIONS

Drug Toxicity

Systemic toxic reactions to local anesthetics primarily involve the CNS and the cardiovascular system [see Table 14]. The initial symptoms are light-headedness and dizziness, followed by visual and auditory disturbances. Convulsions and respiratory arrest may ensue and necessitate treatment and resuscitation.

The use of neuraxial analgesic adjuncts (e.g., opioids, clonidine, epinephrine, and neostigmine) decreases the dose of local anesthetic required, speeds recovery, and improves the quality of analgesia. The side effects of such adjuncts include respiratory depression (opioids), urinary retention (opioids), tachycardia (epinephrine), hypotension (clonidine), and nausea and vomiting (neostigmine, opioids).

Neurologic Complications

The incidence of neurologic complications ranges from 2 in 10,000 to 12 in 10,000 with epidural anesthesia and from 0.3 in 10,000 to 70 in 10,000 with spinal anesthesia.^{49,50} The most common serious complication is neuropathy, followed by cranial nerve palsy, epidural abscess, epidural hematoma, anterior spinal artery syndrome, and cranial subdural hematoma [see Table 12]. Vigilance and routine neurologic testing of sensory and motor function are of paramount importance for early detection and treatment of these potentially disastrous complications.

Table 12 Predicted Incidence of Complications of Regional Anesthesia³⁹

Complication	Incidence	Rate per 10,000 Population	Remarks
Paraplegia	≈ 1:100,000	0.1	
Permanent nerve injury			
Spinal	1–3:10,000	1–3	
Epidural	0.3–10:10,000	0.03–10	
Peripheral nerve block	≈ 1:5,000	2	2% brachial plexus neuropraxia lasting > 3 mo
Epidural hematoma	≈ 1:150,000 (epidural)	0.07	≈ 1:1,000,000 (spontaneous)
	≈ 1:200,000 (spinal)	0.05	≈ 1:14,000 (USA)
			≈ 1:2,250,000 (Europe)
			≈ 1:10,000 (spontaneous)
Epidural abscess	1:2,000–1:7,500	0.7–5.0	
Transient neural complications	1:1,000–1:10,000 (epidural)	1–10 (epidural)	
	1:125–1:2,500 (spinal)	4–80 (spinal)	
Transient radicular irritation (spinal)	Up to 1:3 (heavy lidocaine and mepivacaine)	3,000	
Cardiac arrest	≈ 1:1,500 (spinal)	5 (spinal)	
	≈ 1:3,000 (local anesthesia)	3 (local anesthesia)	
	≈ 1:10,000 (epidural)	1 (epidural)	
	≈ 1:10,000 (regional blocks)	1 (regional)	
Post–dural puncture headache	≈ 1:100	100	80% following inadvertent dural tap
	≈ 1:10 (day surgery)	1,000	Blood patch 70–100%
			Immediate success, but headaches recur in 30–50%
Backache	< 1 hr surgery ≈ 20%	2,000	GA = LA
	> 4 hr surgery ≈ 50%	5,000	
Urinary dysfunction	≈ 1:50	200	
Pneumothorax	≈ 1:20 (supraclavicular blocks)	500	
Systemic LA toxicity	≈ 1:10,000 (epidural)	1	
	≈ 1:1,500 (regional blocks)	7	
Cerebral seizures	≈ 1:4,000 (intravenous regional anesthesia)	2.5	Axillary ≈ 1:1,000
	≈ 1:500 (brachial plexus)	20	Supraclavicular ≈ 1:125
Eye blocks			
Retrobulbar hemorrhage	1:250–1:20,000	0.5–40	
Brainstem anesthesia	≈ 1:700	15	
Globe perforation	≈ 1:10,000	1	
Ptosis—transient after eye block	≈ 1:2 at 24 hr	5,000	
	≈ 1:5 at 1 mo	2,000	
Diplopia—transient after eye block	8–70%	800–7,000	

GA = general anesthesia; LA = local anesthesia.

Transient Neurologic Symptoms

The term *transient neurologic symptoms* (TNSs) refers to backache with pain radiating into the buttocks or the lower extremities after spinal anesthesia. It occurs in 4 to 33% of patients, typically 12 to 36 hours after the resolution of spinal anesthesia, and lasts for 2 to 3 days.⁵¹ TNSs have been

described after intrathecal use of all local anesthetics but are most commonly noted after administration of lidocaine, in the ambulatory surgical setting, and with the patient in the lithotomy position during operation. Discomfort from TNSs is self-limited and can be effectively treated with NSAIDs.

Table 13 Pharmacology of Anticoagulant Agents

Drug	Coagulation Tests		Time to Peak Effect	Time to Normal Hemostasis after Discontinuation
	INR	PTT		
Heparin				
IV	↔	↑↑	min	4–6 hr
SC	↔	↑	1 hr	4–6 hr
LMWH	↔	↔	2–4 hr	12 hr
Warfarin	↑↑	↔	2–6 days	4–6 days
Aspirin	↔	↔	hr	5–8 days
Thrombolytic agents (t-PA, streptokinase)	↔	↑↑	min	1–2 days

↑↑ = clinically significant increase; ↑ = possibly clinically significant increase; ↔ = clinically insignificant increase or no effect; INR = international normalized ratio; LMWH = low-molecular-weight heparin; PTT = partial thromboplastin time; t-PA = tissue plasminogen activator.

Post-Dural Puncture Headache

Use of small-gauge pencil-point needles for spinal anesthesia is associated with a 1% incidence of PDPH. The incidence of PDPH after epidural analgesia varies substantially because the risk of inadvertent dural puncture with a Tuohy needle is directly dependent on the anesthesiologist's training. PDPH is characteristically aggravated by upright posture and may be associated with photophobia, neck stiffness, nausea, diplopia, and tinnitus. Meningitis should be considered in the differential diagnosis. Although PDPH is not life-threatening, it carries substantial morbidity in the form of restricted activity. Medical treatment with bed rest, IV fluids, NSAIDs, and caffeine is only moderately effective. An epidural blood patch is the treatment of choice: the success rate is approximately 70%.

Recovery

Admission to the postanesthetic care unit (PACU) is appropriate for patients whose vital signs are stable and whose pain is adequately controlled after emergence from

anesthesia. Patients requiring hemodynamic or respiratory support may be admitted to the PACU if rapid improvement is expected and appropriate monitoring and personnel are available. Hemodynamic instability, the need for prolonged respiratory support, and poor baseline condition mandate admission to the ICU. Common complications encountered in the PACU include postoperative pulmonary insufficiency, cardiovascular instability, acute pain, and nausea and vomiting [see Table 15]. These complications are discussed in greater detail elsewhere [see 8:5 *Pulmonary Insufficiency*, 8:2 *Acute Cardiac Dysrhythmia*, 1:6 *Postoperative Pain*, and ECP:5 *Patient Safety in Surgical Care: A Systems Approach*].

Special Scenarios

DIFFICULT AIRWAY

Airway management is a pivotal component of patient care because failure to maintain airway patency and ventilation can lead to permanent disability, brain injury, or death. The difficult airway should be managed in accordance with contemporary airway guidelines, such as the protocols established by the ASA, to reduce the risk of adverse outcomes during attempts at ventilation and intubation. (The ASA protocols may be accessed on the organization's Web site: <http://www.asahq.org/Newsletters/2005/11-05/2003TraumaAlgorithm.html>). The emphasis on preserving spontaneous ventilation and the focus on awake intubation options are central themes whose importance cannot be overemphasized.

It is crucial that all patients who are undergoing difficult or prolonged airway instrumentation be appropriately treated with topical anesthesia, sedation, and monitoring so as to ensure adequate ventilation and to attenuate, detect, and treat harmful neuroendocrine responses that can cause

Table 15 Pharmacologic Treatment of Postoperative Nausea and Vomiting⁸

Agent	Dose	Comments
Propofol	10 mg IV, repeated dose	[See Table 8]
Ondansetron	4.0–8.0 mg IV	Highly effective, costly; headache, constipation, transiently increased LFTs
Dexamethasone	4.0–8.0 mg IV	Adrenocortical suppression, delayed wound healing, fluid retention, electrolyte disturbances, psychosis, osteoporosis
Droperidol	0.5–1.0 mg IV	Sedation, restlessness, dysphoria, dysrhythmia (?)
Metoclopramide	10–20 mg IV	Avoid in bowel obstruction, extrapyramidal reactions
Scopolamine	0.1–0.6 mg SC, IM, IV	Muscarinic side effects, somnolence
Dimenhydrinate	25–50 mg IV	Drowsiness, dizziness

IM = intramuscular; IV = intravenous; LFT = liver function test; SC = subcutaneous.

Table 14 Local Anesthetics for Infiltration Anesthesia: Maximum Doses* and Duration of Action

Drug	Without Epinephrine		With Epinephrine (1:200,000)	
	Maximum Dose (mg)	Duration of Action (min)	Maximum Dose (mg)	Duration of Action (min)
Chloroprocaine	800	15–30	1,000	3–90
Lidocaine	300	30–60	500	120–360
Mepivacaine	300	45–90	500	120–360
Prilocaine	500	30–90	600	120–360
Bupivacaine	175	120–240	225	180–420
Etidocaine	300	120–180	400	180–420

*Recommended maximum dose can be given to healthy, middle-aged, normal-sized adults without toxicity. Subsequent doses should not be given for at least 4 hours. Doses should be reduced during pregnancy.

myocardial ischemia, bronchospasm, and intracranial hypertension. Extubation is stressful as well and may be associated with intense mucosal stimulation and exaggerated glottic closure reflexes, resulting in laryngospasm and, possibly, pulmonary edema secondary to vigorous inspiratory efforts against an obstructed airway. Laryngeal incompetence and aspiration can also occur after extubation. Removal of an endotracheal tube from a known or suspected difficult airway should ideally be performed over a tube exchanger so as to facilitate emergency reintubation.

Alternatives to standard oral airways, masks, introducers, exchangers, laryngoscopes, and endotracheal tubes now exist that offer more options, greater safety, and better outcomes. It would be naive to believe that any single practitioner could master every new airway protocol and device. To keep up with technical and procedural advances, university hospital program directors should consider incorporating technical skill laboratories and simulator training sessions into their curricula.

MORBID OBESITY

Morbid obesity represents the extreme end of the overweight spectrum and is usually defined as a body mass index higher than 40 kg/m² [see 5:7 *Surgical Treatment of Morbid Obesity*].⁵² It poses a formidable challenge to health care providers in the OR, the postoperative recovery unit, and the ICU. The major concerns in the surgical setting are the possibility of a difficult airway, the increased risk of known or occult cardiorespiratory compromise, and various serious technical problems related to positioning, monitoring, vascular access, and transport. Additional concerns are the potential for underlying hepatic and endocrine disease and the effects of altered drug pharmacokinetics and pharmacodynamics. For the morbidly obese patient, there is no such thing as minor surgery.

Initial management should be based on the assumptions that (1) a difficult airway is likely; (2) the patient will be predisposed to hiatal hernia, reflux, and aspiration; and (3) rapid arterial desaturation will occur with induction of anesthesia as a consequence of decreased functional residual capacity and high basal oxygen consumption. Often the safest option is an awake fiberoptic intubation with appropriate topical anesthesia and light sedation. In expert hands, this technique is extremely well tolerated and can usually be performed in less than 10 minutes.⁵³ Morbidly obese patients often are hypoxemic at rest and have an abnormal alveolar-arterial oxygen gradient caused by ventilation-perfusion mismatching. The combination of general anesthesia and the supine position exacerbates alveolar collapse and airway closure. Mechanical ventilation, weaning, and extubation may be difficult and dangerous, especially in the presence of significant obstructive sleep apnea. Postoperative pulmonary complications (e.g., pneumonia, aspiration, atelectasis, and emboli) are common.⁵⁴

Morbid obesity imposes unusual loading conditions on both sides of the heart and the circulation, leading to the progressive development of insulin resistance, atherogenic dyslipidemias, systemic and pulmonary hypertension, ventricular hypertrophy, and a high risk of premature coronary artery disease and biventricular heart failure. Perioperative cardiac morbidity and mortality are therefore significant problems. Untoward events can happen suddenly,

and resuscitation is extremely difficult. Cardiorespiratory compromise may be attenuated by effective postoperative pain control that permits early ambulation and effective ventilation. Surgical site infection and dehiscence may result in difficult reoperation and prolonged hospitalization.

MALIGNANT HYPERTHERMIA

MH is a rare but potentially fatal genetic condition characterized by life-threatening hypermetabolic reactions in susceptible individuals after the administration of volatile anesthetics or depolarizing muscle relaxants.⁵⁵ Abnormal function of the sarcoplasmic reticulum calcium release channel in skeletal muscle has been identified as a possible underlying cause.

In making the diagnosis of MH, it is important to consider other possible causes of postoperative temperature elevation. Such causes include inadequate anesthesia, equipment problems (e.g., misuse or malfunction of heating devices, ventilators, or breathing circuits), local or systemic inflammatory responses (either related or unrelated to infection), transfusion reaction, hypermetabolic endocrinopathy (e.g., thyroid storm or pheochromocytoma), neurologic catastrophe (e.g., intracranial hemorrhage), and reaction to or abuse of a drug.

Immediate recognition and treatment of a fulminant MH episode are essential for preventing morbidity and mortality. Therapy consists of discontinuing all triggers, instituting aggressive cooling measures, giving dantrolene in an initial dose of 2.5 mg/kg, and administering 100% oxygen to compensate for the tremendous increase in oxygen use and carbon dioxide production. An indwelling arterial line, central venous access, and bladder catheterization are indispensable for monitoring and resuscitation. Acidosis, hyperkalemia, and malignant dysrhythmias must be rapidly treated, with the caveat that calcium channel blockers are contraindicated in this setting. Maintenance of adequate urine output is of paramount importance and may be facilitated by the clinically significant amounts of mannitol contained in commercial dantrolene preparations. When the patient is stable and the surgical procedure is complete, monitoring and support are continued in the ICU, where repeat doses of dantrolene may be needed to prevent or treat recrudescence of the disease.⁵⁵

MASSIVE TRANSFUSION

Massive blood transfusion, defined as the replacement of a patient's entire circulating blood volume in less than 24 hours, is associated with significant morbidity and mortality. Management of massive transfusion requires an organized multidisciplinary team approach and a thorough understanding of associated hematologic and biochemical abnormalities and subsequent treatment options.

Patients suffering from shock as a result of massive blood loss often require transfusions of packed red blood cells, platelets, fresh frozen plasma, and cryoprecipitate to optimize oxygen-carrying capacity and address dilutional and consumptive loss of platelets and clotting factors [see 8:3 *Shock and 1:4 Bleeding and Transfusion*]. Transfusion of large amounts of blood products into a critically ill patient can lead to coagulopathies, hyperkalemia, acidosis, citrate intoxication, fluid overload, and hypothermia.⁵⁶ Therapy should be guided by vital signs, urine output, pulse oximetry, electrocardiography, capnography, invasive hemodynamic

monitoring, serial arterial blood gases, biochemical profiles, and bedside coagulation screens. Fluids should be administered through large-bore cannulas connected to modern countercurrent warming devices. Shed blood should be salvaged and returned to the patient whenever possible. In refractory cases, transcatheter angiographic embolization techniques should be considered for control of bleeding.

Hemostatic agents, such as procoagulants (desmopressin, recombinant factor VIIa) and antifibrinolytics (aprotinin, tranexamic acid, ϵ -aminocaproic acid), have been used extensively in surgical procedures associated with considerable blood loss (e.g., solid organ transplantation, cardiac and orthopedic surgery [see 1:4 *Bleeding and Transfusion*]).⁵⁷ Although they are effective at reducing blood loss, a serious concern is the increased risk for thrombosis. Aprotinin, a serine protease inhibitor with unique antifibrinolytic and hemostatic properties, very effectively decreases blood loss and transfusion requirements, as well as attenuates potentially harmful inflammatory responses and minimizes reperfusion injury. However, recent evidence indicates that it may be associated with increased morbidity⁵⁸ (renal failure) and mortality,⁵⁹ so its availability has been suspended.⁶⁰ Recombinant factor VIIa was originally approved for hemophiliacs who developed antibodies against either factor VIII or factor IX. It may prove useful for managing hemorrhage deriving from trauma or surgery when standard interventions have failed.⁶¹

HYPOTHERMIA

Significant decreases in core temperature are common during anesthesia and surgery as a consequence of exposure to a cold OR environment and of disturbances in normal protective thermoregulatory responses. Patients lose heat through conduction, convection, radiation, and evaporation, especially from large wounds and during major intracavitary procedures. Moreover, effective vasoconstrictive reflexes and both shivering and nonshivering thermogenesis are severely blunted by anesthetics.⁶² Neonates and the elderly are particularly vulnerable.

Hypothermia may confer some degree of organ preservation during ischemia and reperfusion. For example, in cardiac surgery, hypothermic cardiopulmonary bypass is a common strategy for protecting the myocardium and the CNS. Intentional hypothermia has also been shown to improve neurologic outcome and survival in comatose victims of cardiac arrest. Perioperative hypothermia can have significant deleterious effects as well, however, including myocardial ischemia, surgical site infection, increased blood loss and transfusion requirements, and prolonged anesthetic recovery and hospital stay.

The sensation of cold is highly uncomfortable for the patient, and shivering impedes monitoring, raises plasma catecholamine levels, and exacerbates imbalances between oxygen supply and demand by consuming valuable energy for involuntary muscular activity. It is therefore extremely important to measure the patient's temperature and maintain thermoneutrality. Increasing the ambient temperature of the OR and applying modern forced-air warming systems are the most effective techniques available. In addition, all IV and irrigation fluids should be heated. After the patient has been transferred from the OR, aggressive treatment of

hypothermia with these techniques should be continued as necessary. Shivering may also be reduced by means of drugs such as meperidine, nefopam, tramadol, physostigmine, ketamine, methylphenidate, and doxapram.⁶³

INTRAOPERATIVE AWARENESS

One of the goals of anesthesia is to produce a state of unconsciousness during which the patient neither perceives nor recalls noxious surgical stimuli. When this objective is not met, awareness occurs, and the patient will have explicit or implicit memory of intraoperative events. In some instances, intraoperative awareness develops because human error, machine malfunction, or technical problems result in an inappropriately light level of anesthesia. In others (e.g., when the patient is severely hemodynamically unstable or efforts are being made to avoid fetal depression during cesarean section), the light level of anesthesia may have been intentionally chosen. Regardless of the cause, intraoperative awareness is a terrifying experience for the patient and has been associated with serious long-term psychological sequelae.⁶⁴ Prevention of awareness depends on regular equipment maintenance, meticulous anesthetic technique, and close observation of the patient's movements and hemodynamic responses during operation. CNS monitoring may reduce the risk of intraoperative awareness, particularly when anesthesia is maintained exclusively by intravenous drugs (total intravenous anesthesia).³⁴

ANAPHYLAXIS

Allergic reactions range in severity from mild pruritus and urticaria to anaphylactic shock and death. Inciting agents include, but are not limited to, antibiotics, contrast agents, blood products, volume expanders, protamine, aprotinin, narcotics, induction agents, muscle relaxants, latex,⁶⁵ and, rarely, local anesthetic solutions. Many drug additives and preservatives have also been implicated.

True anaphylaxis presents shortly after exposure to an allergen and is mediated by chemicals released from degranulated mast cells and basophils. Manifestations usually include dramatic hypotension, tachycardia, bronchospasm, arterial oxygen desaturation, and cutaneous changes. Laryngeal edema can occur within minutes, in which case, the airway should be secured immediately. Anaphylaxis can mimic heart failure, asthma, pulmonary embolism, and tension pneumothorax. Treatment involves withdrawing the offending substance and administering oxygen, fluids, and epinephrine, followed by IV steroids, bronchodilators, and histamine antagonists. Prolonged intubation and ICU monitoring may be required until symptoms resolve. Appropriate skin and blood testing should be done to identify the causative agent.

PERIOPERATIVE DYSRHYTHMIAS

In 2005, current scientific developments in the acute treatment of cerebrovascular, cardiac, and pulmonary disease were merged with the evolving discipline of evidence-based medicine to produce the most comprehensive set of resuscitation standards ever created: a 14-part document from the American Heart Association entitled "2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care."⁶⁶ This document addresses a wide array of key issues in both in-hospital and out-of-hospital resuscitation, including a recommendation for

confirmation of tube position after endotracheal intubation and a warning about the danger associated with unintentional massive auto-positive end-expiratory pressure.

As regards the impact the new guidelines have on the management of cardiopulmonary resuscitation, an increase in ratios of compression to ventilation ratios (to 30:2) and an emphasis on effective chest compressions (“push hard, push fast”) are suggested. In addition, early chest compressions before defibrillation, a one-shock sequence for defibrillation as opposed to a three-shock sequence, and avoidance of prolonged interruption of chest compressions are recommended. For wide QRS dysrhythmias, amiodarone continues to be the drug of choice. It may also be administered for ventricular fibrillation or for pulseless ventricular tachycardia that does not respond to cardiopulmonary resuscitation, cardioversion, and a vasopressor.

Amiodarone is a complex, powerful, and broad-spectrum agent that inhibits almost all of the drug receptors and ion channels conceivably responsible for the initiation and propagation of cardiac ectopy, irrespective of underlying ejection fraction, accessory pathway conduction, or anatomic substrate. It does, however, have potential drawbacks, such as its relatively long half-life, its toxicity to multiple organs, and its complicated administration scheme. Furthermore, amiodarone is a potent noncompetitive alpha and beta blocker, which has important implications for anesthetized, mechanically ventilated patients who may be debilitated and experiencing volume depletion, abnormal vasodilation, myocardial depression, and fluid, electrolyte, and acid-base abnormalities. That said, no other drug in its class has ever demonstrated a significant benefit in randomized trials addressing cardiac arrest in humans.

Amiodarone is effective in both children and adults, and it can be used for prophylaxis and treatment. The recommended cardiac arrest dose is a 300 mg IV bolus. In less acute situations (e.g., wide-complex tachycardia), an initial 150 mg dose should be administered slowly over 10 minutes, and one or two additional boluses may be given similarly. A loading regimen is then initiated, first at 1 mg/min for 6 hours and then at 0.5 mg/min for 18 hours.

Vasopressin (antidiuretic hormone) continues to be listed as an alternative to epinephrine in the ventricular tachycardia/ventricular fibrillation protocol. Vasopressin is an integral component of the hypothalamic-pituitary-adrenal axis and the neuroendocrine stress response. The recommended dose for an adult in fibrillatory arrest is 40 units in a single bolus. For vasodilatory shock states associated with sepsis, hepatic failure, or vasomotor paralysis after cardiopulmonary bypass, infusion at a rate of 0.01 to 0.04 units/min may be particularly useful. Vasopressin is neither recommended nor forbidden in cases of pulseless electrical activity or asystolic arrest, and it may be substituted for epinephrine.

Table 16 Cardiac Conditions Associated with Risk of Adverse Outcome from Endocarditis for Which Prophylaxis Is Reasonable⁶⁷

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
Previous infective endocarditis
Congenital heart disease (CHD)*
Unrepaired cyanotic CHD, including palliative shunts and conduits
Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure†
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
Cardiac transplant recipients who develop cardiac valvulopathy

*Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.

†Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.

ANTIBIOTIC PROPHYLAXIS

Recently, the American Heart Association has revised the guidelines for administration of antibiotic drugs prophylactically to prevent infective endocarditis.⁶⁷ Infective endocarditis prophylaxis is no longer recommended for mitral valve prolapse or for the stenotic or regurgitant cardiac lesions associated with rheumatic heart disease [see Table 16]. A suggested antibiotic regimen is provided in Table 17.

Table 17 Antibiotic Protocol⁶⁷

Situation	Agent	Regimen: Single Dose 30–60 min before Procedure	
		Adults	Children
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin or cefazolin or ceftriaxone	2 g IM or IV	50 mg/kg IM or IV
		1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillins or ampicillin oral	Cephalexin*† or clindamycin or azithromycin or clarithromycin	2 g	50 mg/kg
		600 mg	20 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone† or clindamycin	500 mg	15 mg/kg
		1 g IM or IV	50 mg/kg IM or IV
		600 mg IM or IV	20 mg/kg IM or IV

IM = intramuscular; IV = intravenous.

*Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.

†Cephalosporins should not be used in a person with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.

Financial disclosure: none reported.

Garth H. Utter, MD, MSc, FACS, Robert C. Gosselin, MT, and John T. Owings, MD, FACS

A surgeon is frequently one of the first people to be called when a patient experiences massive hemorrhage. “Massive hemorrhage” is usually not hard to recognize in practice, but it can be defined as hemorrhage requiring at least 10 units of cellular blood products within 24 hours. To treat such a patient appropriately, the surgeon must rapidly and simultaneously accomplish three tasks: identify the source or cause of the bleeding, stop or limit the bleeding, and restore the patient’s circulation.

Causes fall into two main categories: (1) conditions involving loss of vascular integrity, such as a patient with bleeding from a peptic ulcer or a trauma patient with a severe liver laceration, and (2) conditions involving a derangement of the hemostatic process. Typically, massive hemorrhage begins with a loss of vascular integrity, but derangements of hemostasis frequently develop as a secondary problem and play a major role in the exacerbation of such hemorrhage. In this section, we focus on the immediate concerns to keep the patient alive with particular attention to how to address the associated coagulopathy. We consider derangements of hemostasis that are not associated with massive hemorrhage in the next section, "Approach to the Patient with a Derangement of Hemostasis."

If a coagulopathy develops as a result of uncontrolled hemorrhage from loss of vascular integrity, attempting to treat the coagulopathy without controlling the

source is an exercise in futility. Other sections of this text address the anatomic and technical considerations involved in controlling different sites of bleeding [see subcategories under “Bleeding” in the Index]. However, in contrast to the routine conduct of operations, control of the source of massive bleeding requires a fundamentally different mindset.

The goals of operative conduct change from definitive management of all issues to "damage control," in which the salient objective is to address immediately life-threatening problems: restoration of vascular integrity and, to the extent necessary and prudent, restoration of the circulation of the viscera and limbs. Other goals, such as reestablishment of intestinal continuity or closure of the wound, become secondary and can be addressed later if the patient survives. Even selected, more drastic maneuvers for exposure of the site of

bleeding should be considered when the patient is at appreciable risk of death; these apply even if the hemorrhage developed during an elective procedure. For example, right nephrectomy may be warranted to afford exposure of the infrahepatic inferior vena cava, or deliberate division of a common iliac artery may be necessary to expose bleeding from the corresponding common iliac vein. Temporary vascular shunts may be helpful to rapidly restore blood flow to ischemic limbs if it is still possible to salvage the limb. However, reperfusion of a large volume of ischemic tissue in the setting of shock can cause severe systemic problems, so expert judgment is necessary to decide whether to try to preserve or amputate the limb in such situations.

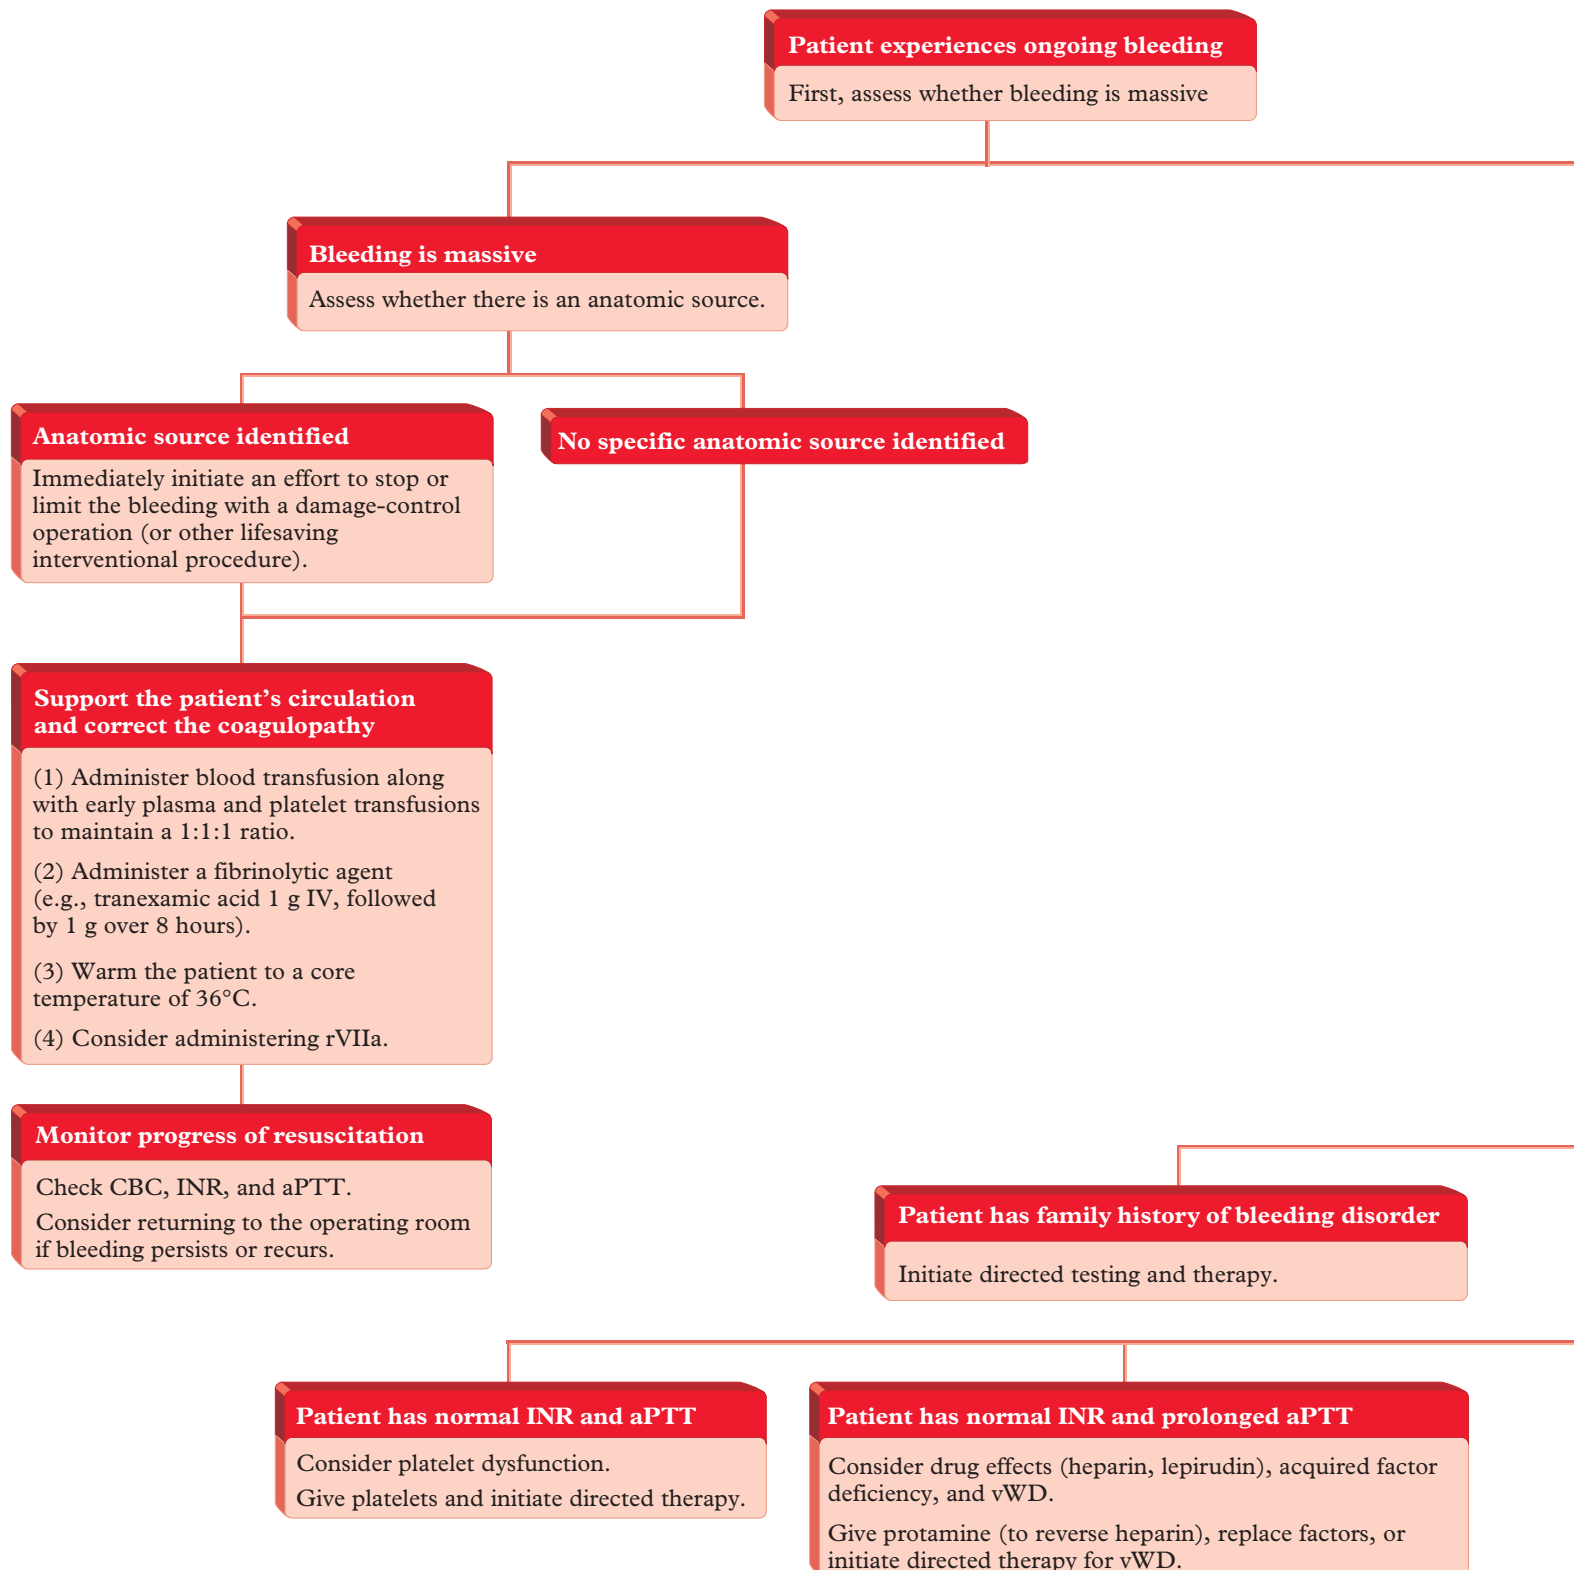

Sometimes, the best option to control massive hemorrhage is not necessarily an open operation. Increasingly, interventional radiologic and endovascular techniques are serving important roles: although long used for control of bleeding from sites not easily managed with open procedures, such as pelvic fractures, they have recently become an accepted approach for some problems traditionally managed with open procedures, such as ruptured abdominal aortic aneurysms,¹ because of the speed of access by an experienced interventionalist. However, the surgeon should be actively involved in decisions to use minimally invasive techniques and should never hesitate to operate if that is the best option in a given situation. Surgeons must individualize their approach to each patient based on their expertise, available resources, and the most current standards of care but be willing to use all tools in their armamentarium.

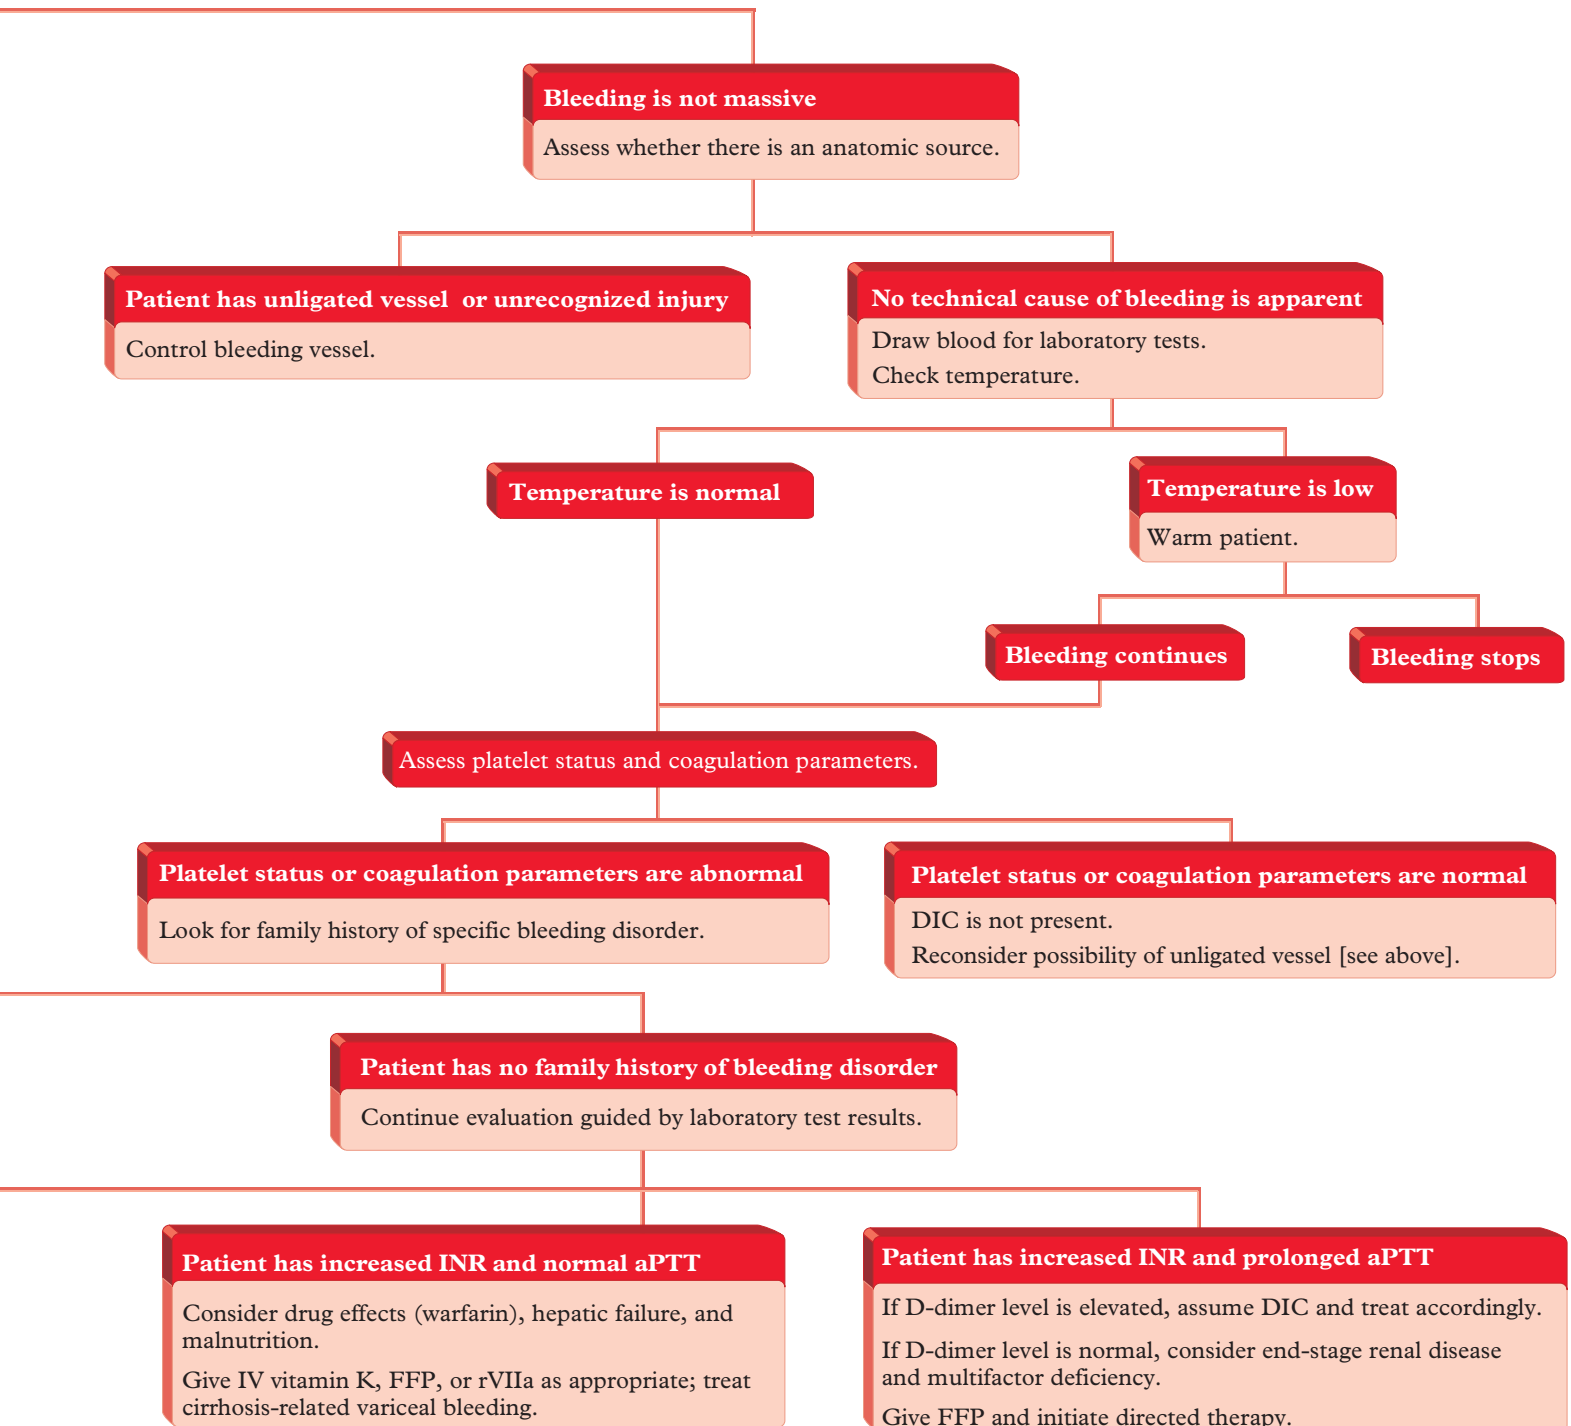

Just as massive hemorrhage should lead the surgeon to reprioritize the goals of an operation, it should also prompt a major shift in the fluid resuscitation strategy. Initially, when there is massive hemorrhage that can be addressed with an operation, resuscitation with blood products and other intravenous (IV) fluids should be implemented only as an adjunct while attempts are made to stop the loss of blood. Although surgeons continue to debate the merits of “permissive hypotension” (the concept that fluid resuscitation before control of hemorrhage should be minimized because it will lead to increased bleeding²), attempts at fluid resuscitation should not delay procedures to control massive hemorrhage, even temporarily.

When massive bleeding exists and direct control of the site of bleeding is under way, the decision to transfuse should be based primarily on hemodynamic status rather than on the hemoglobin or hematocrit level. These laboratory values do

Approach to the Patient with Hemorrhage

not reflect acute hemorrhage because there is a time lag before these levels equilibrate from fluid shift between the extravascular and vascular compartments and from administration of IV fluids. The goals of transfusion are therefore as much to increase the intravascular volume as to prevent the development of profound deficits in oxygen-carrying capacity. Stabilized patients who are at high risk for recurrent bleeding (e.g., those with a massive liver injury or gastrointestinal (GI) hemorrhage from an unknown source) should receive transfusions up to a level at which, should bleeding recur, enough reserve oxygen-carrying capacity would be available to allow diagnosis and correction of the hemorrhage without significant compromise of oxygen delivery (we advocate a target hematocrit of roughly 30% during this phase). The standard restrictive transfusion strategy used in stable intensive care unit (ICU) patients [see Approach to the Patient with Anemia, *below*] warrants modification in these circumstances because of the higher likelihood of occult active hemorrhage.

Management of the Coagulopathy

It is true that coagulopathy may promote massive hemorrhage and that massive hemorrhage causes a coagulopathy. As a rule, the massively hemorrhaging patient has a coagulopathy out of proportion to the abnormalities reflected with in vitro laboratory tests such as the prothrombin time (PT, commonly expressed as an international normalized ratio [INR]) or activated partial thromboplastin time (aPTT). Coagulopathy most typically occurs when there is massive hemorrhage in concert with injury to a large volume of tissue. Although the nature of this coagulopathy is not precisely defined, it probably involves a number of factors: (1) platelet dysfunction and diminished availability of platelets at the interface between the vascular endothelium and luminal flow; (2) dysfunctional formation of thrombi in the setting of acidosis and hypothermia; (3) accelerated thrombolysis (attributable to dysfunctional thrombosis); and, eventually, (4) consumption of clotting factors.

Increased recognition of this coagulopathy has prompted enthusiasm for administration of plasma and platelets early in the treatment of the patient with massive hemorrhage. This practice, frequently incorporated into a massive transfusion protocol, is described as “1:1:1 transfusion” because the goal is to transfuse one unit of plasma and one of platelets along with each unit of red blood cells (RBCs) such that the ratio stays balanced throughout the resuscitation phase. (Adjustment of these ratios is necessary for centers that use pooled quantities of plasma and/or platelets.) The rationale is that patients are already extensively coagulopathic by the time they manifest thrombocytopenia or prolongation of the INR or aPTT. Thus, during the first several hours during and after massive hemorrhage, plasma and platelets are necessary independent of the laboratory tests and help address a significant contributing factor for persistent hemorrhage.

The concept of liberal, early use of plasma and platelets developed in large part from the recent US-led military campaigns in Iraq and Afghanistan. Initially in those conflicts, the lack of a reliable supply of blood products near the scene of injury—and platelets especially—led to the use of fresh whole blood transfusion. Although fresh whole blood would be impractical in the civilian setting because of logistical issues and the risk of transmitting transfusion-related infections, the perception of improved outcomes associated with its use prompted military surgeons to advocate 1:1:1 transfusion.

Proponents of this approach argue that it restores hemostatic capacity and helps limit hemorrhage, leading to improved survival. Indeed, observational studies suggest that mortality is reduced.³ However, the ratios examined in these studies typically have been calculated retrospectively over relatively long (e.g., 12- or 24-hour) time periods after hemorrhage. Critics emphasize that patients who do not survive long enough to receive early plasma and platelets bias such observational comparisons (i.e., they are classified as receiving a large ratio of RBCs to plasma or platelets because they died early) and that plasma and platelets carry theoretical harms of transfusion-related acute lung injury and bacterial infection, respectively. Despite some uncertainty about the actual merits of the 1:1:1 approach, given that military conflicts have frequently spurred advances in transfusion medicine, it appears likely that the approach will be adopted more widely if the availability of blood products does not limit its application. In the absence of sufficient availability of blood products to allow a 1:1:1 approach, aggressive correction of abnormalities of the INR, aPTT, and platelet count are warranted for patients with massive hemorrhage.

More convincing information supports the use of antifibrinolytic agents in the setting of massive hemorrhage. Aprotinin, tranexamic acid, and ε-aminocaproic acid (Amicar) are known to reduce transfusion requirements in the setting of elective operations (primarily cardiac procedures). Furthermore, a recent large randomized trial, the CRASH-2 trial, showed that patients with or at risk for significant bleeding (i.e., hypotension or tachycardia) from traumatic injury had decreased all-cause and bleeding-related mortality when they received tranexamic acid within 8 hours of injury.⁴ In this study, tranexamic acid was administered intravenously as a 1 g loading dose, followed by an infusion of an additional 1 g over 8 hours. Tranexamic acid did not increase the likelihood of major vascular occlusion events (myocardial infarction, stroke, and pulmonary embolism).

Recombinant activated factor VII (rVIIa) is approved for the treatment of hemophilia in the United States. It has also been advocated for off-label use early in the course of uncontrolled hemorrhage⁵ and intracranial hemorrhage. Although rVIIa can be a rapid and highly specific form of treatment in certain instances of bleeding (e.g., traumatic brain injury in a patient on warfarin), the rationale for its use is not as highly targeted in the setting of massive hemorrhage, during which factor deficiencies are not typically an early abnormality. Two sponsor-initiated international randomized trials of rVIIa in severely injured trauma patients have been performed, and their results—although neither had overwhelming power to detect improved survival—suggest that rVIIa decreases blood transfusions but does not reduce mortality.^{6,7} One recent

report suggested that off-label use of rVIIa in certain populations significantly increased the risk of arterial thromboembolic complications.⁸ In the absence of better designed and conducted studies of patients with massive bleeding, surgeons will need to decide whether use of rVIIa is warranted despite its costs and incompletely understood efficacy and safety profile in this setting. Consensus recommendations have attempted to define appropriate use in light of insufficient evidence.⁹

There is relatively little controversy over the management of hypothermia. As a series of chemical reactions, the coagulation cascade slows with decreasing temperature.¹⁰ Thus, a patient with a temperature lower than 35°C (95°F) clots more slowly and less efficiently than one with a temperature

of 37°C (98.6°F). The resulting coagulopathy cannot be detected by laboratory tests because the laboratory warms the sample to 37°C to run the coagulation assays (INR and aPTT). Thus, bleeding hypothermic patients should be rewarmed, and active measures are warranted if the core temperature is 34.5°C (94.1°F) or lower.¹¹

Relatively new agents have been promulgated to facilitate hemostasis at sites of focal bleeding. QuikClot (Z-Medica, Newington, CT), a granular substance containing the mineral zeolite, and HemCon (HemCon, Inc., Portland, OR), a chitosan-based dressing, have been used in the setting of military trauma. Preliminary information suggests that whereas QuikClot appears to cause superficial burns, HemCon may carry few disadvantages.¹²

Approach to the Patient with a Derangement of Hemostasis

SCORE Not infrequently, surgeons encounter patients with actual or suspected derangements of hemostasis short of massive hemorrhage. These situations range from the preoperative assessment of asymptomatic patients potentially at risk for coagulopathic bleeding to the postoperative management of patients with an observed bleeding diathesis. Although it is still important to rule out the possibility of technical causes of bleeding, surgeons should also be able to recognize coagulopathic bleeding and know how to prevent it when possible or evaluate and manage its most common etiologies when it occurs.

Coagulopathies are varied in their causes, treatments, and prognoses. Although specialized hematologic tests exist to identify rare congenital or acquired clotting abnormalities, our goal in this section is to outline a practical, effective approach to the coagulopathies surgeons see most frequently. The vast majority of these coagulopathies can be diagnosed by means of a brief patient and family history, a review of medications, physical examination, and commonly used laboratory studies—in particular, PT (commonly expressed as an INR), aPTT, complete blood count (CBC), and D-dimer assay.

In the Discussion section later in this chapter, we present an overview of the physiology of hemostasis and consider some of the rarer conditions and theoretical considerations in greater detail.

Exclusion of Technical Causes of Bleeding

It is critical to emphasize that the most common causes of postoperative bleeding, even when it is not massive, are technical: an unligated vessel or an unrecognized injury is much more likely to be the cause of a falling hematocrit than either a drug effect or an endogenous hemostatic defect. Furthermore, if an unligated vessel is treated as though it were an endogenous hemostatic defect (i.e., with transfusions), the outcome is

frequently disastrous. For these reasons, in all cases of ongoing bleeding, the first consideration must always be to exclude a surgically correctable cause.

Ongoing bleeding may be surprisingly difficult to diagnose. Healthy young patients can usually maintain a normal blood pressure until their blood loss exceeds 40% of their blood volume (roughly 2 L). If the bleeding is from a laceration to an extremity, it will be obvious; however, if the bleeding is occurring internally, there may be few physiologic signs until the patient is at high risk for death.

Even when a technical cause of bleeding has seemingly been excluded, the possibility should be reconsidered periodically throughout assessment. Patients who are either unresuscitated or underresuscitated undergo vasospasm that results in decreased bleeding. As resuscitation proceeds, the catecholamine-induced vasospasm subsides and bleeding may recur. Only when the surgeon is confident that a missed injury or unligated vessel is not the cause of the bleeding should other potential causes be investigated.

Initial Assessment of Potential Coagulopathy

The first step in the assessment of a stable patient with a potential coagulopathy is to draw a blood sample. The blood should be drawn into a tube containing ethylenediaminetetraacetic acid (EDTA) for a CBC and into a citrated tube for coagulation analysis (these tubes commonly have purple and blue tops, respectively).

Concomitant with these laboratory tests, it is essential to obtain a personal and family history of bleeding tendencies. A patient who has had dental extractions without major problems or who had a normal adolescence without any history of bleeding dyscrasias is very unlikely to have a congenital or hereditary bleeding disorder.¹³ Alternatively, previous bleeding events and a familial history of bleeding are

both suggestive of a congenital coagulopathy and warrant further testing to diagnose and treat the disorder [see Discussion, Bleeding Disorders, *below*]. Mucosal and superficial bleeding is suggestive of platelet abnormalities, and deep bleeding is suggestive of a factor deficiency. A thorough medication inventory is necessary to assess the possible impact of drugs on laboratory and clinical presentations. In the patient history query, it is advisable to ask explicitly about nonprescription drugs—using expressions such as “over-the-counter drugs,” “cold medicines,” and “Pepto-Bismol”—because unless specifically reminded, patients tend to equate the term “medications” with prescription drugs. If this is not done, many drugs that are capable of influencing hemostasis *in vivo* and *in vitro* (e.g., salicylates, cold and allergy medicines, and herbal supplements) may be missed.

Interpretation of Coagulation Parameters

NORMAL INR, NORMAL APTT

Patients with a normal INR and a normal aPTT who exhibit unexpected bleeding may have impaired platelet activity. Inadequate platelet activity is frequently manifested as persistent oozing from wound edges or as low-volume bleeding. Such bleeding is rarely the cause of exsanguinating hemorrhage, although it may be life-threatening when it occurs in certain locations (e.g., inside the cranium or the pericardium). Inadequate platelet activity may be attributable to an insufficient number of platelets, platelet dysfunction, or a platelet inhibitor. In the absence of a major surgical insult or concomitant coagulopathy, a platelet count of 20,000/ μ L or higher is usually adequate for normal coagulation.^{14,15} There is some disagreement regarding the threshold for platelet transfusion in the absence of active bleeding. Patients undergoing procedures in which even small-vessel oozing is potentially life-threatening (e.g., craniotomy) should be maintained at a higher platelet count (i.e., > 20,000/ μ L). Patients without ongoing bleeding who are not specifically at increased risk for major complications from low-volume bleeding may be safely watched with platelet counts as low as 10,000/ μ L.¹⁶

Oozing in a patient who has an adequate platelet count and normal coagulation parameters may be a signal of platelet dysfunction. The now-routine administration of acetylsalicylic acid (aspirin) and clopidogrel (Plavix) to reduce the risk of myocardial infarction and stroke has led to a rise in the incidence of drug-induced platelet dysfunction. Aspirin causes irreversible platelet dysfunction through the cyclooxygenase pathway. It takes approximately 10 days for sufficient numbers of new platelets to be formed such that the effect of aspirin lapses; however, because the half-life of aspirin is on the order of 2 to 5 hours, new platelet transfusions should be unaffected if at least a day has passed since the last use of aspirin. The platelet dysfunction caused by other nonsteroidal antiinflammatory drugs (e.g., ibuprofen) is reversible and consequently does not generally last as long as that caused by aspirin.

Newer platelet-blocking agents have been found to be effective in improving outcome after coronary angioplasty.¹⁷ These drugs function through different mechanisms. Some, such as abciximab (ReoPro), eptifibatide (Integrilin), and tirofiban (Aggrastat), block the platelet surface receptor glycoprotein (GP) IIb-IIIa, which binds platelets to fibrinogen. Others, such as clopidogrel, ticlopidine (Ticlid), and prasugrel (Effient), target the P2Y₁₂ receptor (also known as the adenosine diphosphate [ADP] receptor). Clopidogrel, the most commonly used among this group, permanently prevents the association of P2Y₁₂ receptors into functional oligomeric complexes. As a result, there is no way to inactivate this medication if the patient experiences bleeding during its therapeutic window, which typically lasts about 5 days from the last dose. In the face of life-threatening bleeding during this interval, it is reasonable to administer platelets based on the rationale that, in large-enough quantities, they may eventually bind all of the active metabolite. Some of the newest drugs in the P2Y₁₂ inhibitor class (which have not yet been evaluated for use in the United States), for example, ticagrelor, are reversible, which may help avoid such difficulties in the future.

von Willebrand disease (vWD), although sometimes associated with a slight prolongation of the aPTT (as a result of decreased factor VIII activity), most commonly shows no abnormalities with both the INR and the aPTT. The clinical expression is variable, but von Willebrand factor (vWF) levels of less than 30% are more likely associated with clinically important bleeding. Confirmation of the diagnosis can be obtained by specialized tests [see Discussion, Bleeding Disorders, *below*]. Correction is accomplished by administering desmopressin, directed therapy (vWF/factor VIII), or cryoprecipitate.

In patients with platelet dysfunction caused by an inhibitor of platelet function, such as an elevated blood urea nitrogen (BUN) level or aspirin, 1-desamino-8-D-arginine vasopressin (desmopressin) is capable of significantly improving the platelet dysfunction.¹⁸ The mechanism of this effect is not entirely understood but appears to involve more complex changes than simply increased release of factor VIII and vWF.

Supratherapeutic effects of the low-molecular-weight heparins (LMWHs) may also manifest with a normal INR and aPTT [see Normal INR, Prolonged aPTT, *below* for a discussion of both unfractionated heparin and the LMWHs].

Less common causes of bleeding in patients with a normal INR and a normal aPTT include factor XIII deficiency, hypofibrinogenemia or dysfibrinogenemia, and derangements in the fibrinolytic pathway [see Discussion, Mechanics of Hemostasis, *below*].

NORMAL INR, PROLONGED APTT

In the absence of a history of significant bleeding, patients with a normal INR and an abnormal aPTT are likely to have a drug-induced coagulation defect. The agent most commonly responsible is unfractionated heparin. Reversal of the heparin effect, if desired, can be

accomplished by administering protamine sulfate. Protamine should be given with caution, however, because it may induce both hyper- and hypocoagulable states.¹⁹ Protamine should also be used with caution because of the potential for allergic reactions, including anaphylaxis. Patients can become sensitized to impurities in protamine if they have previously received it. Also, diabetic patients have been described to become sensitized through their exposure to similar impurities in protamine-containing insulin formulations (e.g., neutral protamine Hagedorn, or “NPH,” insulin).²⁰

Importantly, the aPTT does not detect the anticoagulant activity of LMWHs. Because such heparins exert much of their anticoagulant effect by potentiating antithrombin to inactivate factor Xa rather than factor IIa, an assay that measures anti-Xa activity is needed to measure the anticoagulant effect. However, the anti-Xa effect of the LMWHs may not be as effectively reversed by protamine as the anti-IIa effect of unfractionated heparin. It is currently unclear which agent is best for reversal of LMWHs, but both protamine and rVIIa have been advocated. Whether or not bleeding has occurred, because the standard coagulation tests do not detect the effect of the LMWHs, suspicion for a supratherapeutic effect should be aroused if there is a concern that excessive doses have been administered or clearance has decreased (e.g., renal insufficiency).

One nuance of the anti-Xa laboratory assay is that it may not truly measure the degree of anticoagulation *in vivo*; rather, anti-Xa results for some of the available assays should be interpreted merely as the concentration of LMWH in plasma. Because heparins (including LMWHs) function to a large extent by catalyzing the activity of antithrombin, the therapeutic effect of heparin is critically dependent on adequate antithrombin levels. In fact, acquired antithrombin deficiency (as occurs with trauma and other critical illnesses) is the most common reason for LMWH to have an inadequate effect. The anti-Xa laboratory assay may not account for *in vivo* antithrombin levels, because some methods involve the addition of antithrombin to the test sample as a reagent. Consequently, the results of this assay may not be a reliable guide to the patient's coagulation status.

An additional crucial point is that the administration of plasma (e.g., fresh frozen plasma [FFP]) will not correct the anticoagulant effect of either unfractionated heparin or LMWHs. In fact, given that plasma contains antithrombin and that both unfractionated heparin and LMWHs act by potentiating antithrombin, administration of FFP could actually enhance the heparins' anticoagulant effect.

A variety of direct thrombin inhibitors (e.g., bivalirudin [Hirulog], lepirudin, argatroban, and dabigatran) are currently available in Europe, Asia, and North America.²¹ Many of them cause prolongation of the aPTT. Dabigatran is a new oral direct thrombin inhibitor that has been recently approved for use in the United States for atrial fibrillation. As an oral alternative to warfarin that does not require frequent laboratory tests to monitor its anticoagulant effect, dabigatran may become widely used. It has a variable impact on coagulation assays: the aPTT is typically elevated but may be only moderately prolonged with supratherapeutic levels of dabigatran.²² One disadvantage shared by most of the direct thrombin

inhibitors is that the effects are not reversible; if thrombin inhibition is no longer desired, FFP should be given to attempt to correct the aPTT. Because the inhibitor that is circulating but not bound at the time of FFP administration will bind the prothrombin in the FFP, the amount of FFP required to correct the aPTT may be greater than would be needed with a simple factor deficiency.

Hemophilia is also associated with prolongation of the aPTT. It can cause spontaneous bleeding or prolonged bleeding after a surgical or traumatic insult. As noted, hemophilia is rare in the absence of a personal or family history of the disorder. Although hemophilia can occur as an acquired autoimmune condition with production of antibodies against clotting factors, the most common forms of hemophilia are inherited and involve deficiencies of factors VIII, IX, and XI (hemophilia A, hemophilia B [Christmas disease], and hemophilia C, respectively). As X-linked recessive disorders, hemophilias A and B occur almost exclusively in males. The clinical presentations of hemophilia A and hemophilia B are similar: hemarthroses are the most common clinical manifestations, ultimately leading to degenerative joint deformities. Spontaneous bleeding may also occur, resulting in intracranial hemorrhage, large hematomas in the muscles of extremities, hematuria, and GI bleeding. Certain types of vWD can result in a deficiency of factor VIII and thus present like hemophilia A. Factor XI deficiency is relatively common in Jewish persons but rarely results in spontaneous bleeding. Such deficiency may result in bleeding after oral operations and trauma; however, a number of major procedures (e.g., cardiac bypass surgery) do not result in postoperative bleeding in this population.²³

In contrast to depletion of natural anticoagulants such as antithrombin and protein C, depletion of procoagulant factors rarely gives rise to significant manifestations until it is relatively severe. Typically, no laboratory abnormalities result from depletion of procoagulant factors until factor activity levels fall below 40% of normal, and clinical abnormalities are frequently absent even when factor activity levels fall to only 10% of normal. This tolerance for subcritical degrees of depletion is a reflection of the built-in redundancies in the procoagulant pathways.

If hemophilia is suspected, specific factor analysis is indicated. Appropriate therapy involves administering the deficient factor or factors. Hemophilic patients who have undergone extensive transfusion therapy may pose a particular challenge: massive transfusions frequently lead to the development of antibodies that make subsequent transfusion or even directed therapy impossible. Accordingly, several alternatives to transfusion or directed factor therapy (e.g., rVIIa) have been developed for use in this population.

Other conditions may also have an isolated effect on the aPTT. Drotrecogin alfa (i.e., activated protein C), a medication approved for treatment of certain subgroups of patients with sepsis, may prolong the aPTT. Its use is contraindicated in the presence of active hemorrhage, but if bleeding should arise during its use, cessation of the infusion should suffice as a result of its short half-life. Lupus anticoagulant and contact factor deficiency can also cause prolongation of the aPTT; however, these phenomena do not clinically result in a hypocoagulable state.

INCREASED INR,
NORMAL APTT

An increased INR in association with a normal aPTT is potentially a more ominous finding in a patient with a coagulopathy. Any of a number of causes, all centering on factor deficiency, may be responsible.

An elevated INR occurs with the administration of vitamin K antagonists (e.g., warfarin), with variable effects on the aPTT. If the aPTT is normal, this usually demonstrates that warfarin was only recently started (usually < 3 days of treatment) or has been underdosed. Such a coagulopathy is the result of a pure factor deficiency, and its degree is proportional to the prolongation of the INR. Because warfarin acts by disrupting vitamin K metabolism, the coagulopathy may be corrected by giving vitamin K [see Table 1], but this process takes several hours for additional proteins to be synthesized.²⁴ If the patient is actively bleeding, vitamin K should still be given, but the primary corrective measures should be to administer FFP and/or rVIIa. FFP should be administered in an amount proportional to the patient's size and the relative increase in the INR, whereas rVIIa should be administered at a dose of 15 to 90 µg/kg. The INR should subsequently be rechecked to ensure that correction has been achieved. Because rVIIa has a relatively short half-life, in general, it should be used as an adjunct to FFP rather than a replacement for it. Aside from the time delay involved, the main potential disadvantage of vitamin K replacement therapy is that if the patient is to be reanticoagulated with warfarin in the near future, dosing will be difficult because the patient will exhibit resistance to warfarin for a variable period.

Cirrhosis is arguably the most serious of the causes of an elevated INR. It is a major problem not so much because of the coagulopathy itself but because of the associated deficits in wound healing and immune function that result from dysfunction of reticuloendothelial cells and hepatocytes.

Generally, factor replacement should be instituted with FFP, but use of rVIIa is reasonable in the setting of active hemorrhage or any intracranial hemorrhage. Although to date there is little information on its efficacy in this particular setting, the administration of rVIIa, 20 to 40 µg/kg, would be a reasonable approach. If the bleeding is a manifestation of portal hypertension (as in variceal bleeding), emergency portal decompression—typically via transjugular intrahepatic portosystemic shunting—should be considered. Modest elevations of the INR in patients with cirrhosis who are not actively bleeding, have not recently undergone operation, and are not specifically at increased risk for life-threatening hemorrhage may be observed without correction.

INCREASED INR,
PROLONGED APTT

Increases in both the INR and the aPTT may be the most problematic finding of all. When both assays show increases, the patient is likely to have multiple factor deficiencies; possible causes include disseminated intravascular coagulation (DIC), severe hemodilution, and renal failure with severe nephrotic syndrome. However, when dramatic elevations of the aPTT and the INR occur that are out of proportion to the patient's clinical status, the problem may simply be that the specimen tube was not adequately filled. If a life-threatening coagulopathy seems unlikely, the blood sample should be redrawn and the tests repeated.

Hemodilution and nephrotic syndrome result in a coagulopathy that is attributable to decreased concentration of coagulation proteins. Dilutional coagulopathy may occur when a patient who is given a large volume of packed RBC units is not also given coagulation factors.²⁵ Because of the tremendous redundancy of the hemostatic process, pure dilutional coagulopathy is rare. It is considered an unlikely diagnosis until after one full blood volume has been replaced (as when a patient requires 10 units of packed RBCs to

Table 1 Management of the Patient with an Increased International Normalized Ratio

Indication		Recommended Treatment
No significant bleeding	INR above therapeutic range but < 5.0	Lower or hold the next dose
	INR > 5.0 but < 9.0	
	Rapid reduction of INR is not required	In the absence of additional risk factors for bleeding, withhold next 1–2 doses; alternatively, withhold next dose and give vitamin K, 1.0–2.5 mg orally
	Rapid reduction of INR is required	Give vitamin K, 1.0–2.0 mg p.o.; expected reduction of INR should occur within 24 hr
	INR > 9.0	Give vitamin K, 3.0–5.0 mg p.o.; expected reduction of INR should occur within 24 hr
Serious bleeding	Any elevation of INR	Give vitamin K, 10 mg IV, supplemented with FFP, prothrombin complex concentrate, or rVIIa; further vitamin K supplementation may be required every 12 hr
Life-threatening bleeding	Any elevation of INR	Give FFP, prothrombin complex concentrate, or rVIIa supplemented with vitamin K 10 mg IV, repeated as necessary

FFP = fresh frozen plasma; INR = international normalized ratio; rVIIa = recombinant activated factor VII.

maintain a stable hematocrit). Nephrotic syndrome is associated with loss of plasma proteins (including coagulation factors) from the kidneys.

Both hemodilution and nephrotic syndrome should be distinguished from DIC (which is a consumptive rather than a dilutional process²⁶), although, on occasion, this distinction is a difficult one to make. A blood sample should be sent for D-dimer assay. If the D-dimer level is low (< 1,000 ng/mL), DIC is unlikely; if it is very high (> 2,000 ng/mL) and there is no other clear explanation (e.g., a complex pelvic fracture), DIC is more likely than dilutional coagulopathy. Treatment of dilutional coagulopathy should be directed at replacement of lost factors. FFP should be given first, followed by cryoprecipitate, calcium, and platelets. Transfusion should be continued until the coagulation parameters are corrected and the bleeding stops.

The term “DIC” refers to the phenomenon of diffuse, disorganized activation of the clotting cascade within the vascular space. It does not occur as an isolated process; rather, it is always secondary to an underlying problem. It typically results either from an overwhelming clotting stimulus (e.g., massive crush injury, overwhelming infection, or transfusion reaction) or from a more moderate clotting stimulus in the context of shock. The underlying problem that manifests as DIC has a range of severity, with mild and moderate cases represented by anything from a subclinical process to the development of organ dysfunction. One school of thought is that the systemic inflammatory response syndrome and DIC are simply different manifestations of the same process. However, severe cases are what surgeons traditionally think of as DIC: bleeding in the context of fibrinolysis and consumption of coagulation factors. Severe DIC arises when congestion of the microvasculature with thrombi occurs, resulting in large-scale activation of the fibrinolytic system. This fibrinolytic activity results in breakdown of clot at previously hemostatic sites of microscopic injury (e.g., endothelial damage) and macroscopic injury (e.g., IV catheter sites, fractures, or surgical wounds), as well as degradation of fibrinogen systemically. Bleeding and reexposure to tissue factor stimulate activation of factor VII with increased coagulation activity; thus, microthrombi are formed, and the vicious circle continues.

Beyond recognition and correction of the underlying problem causing DIC and the associated coagulopathy, the diagnosis of DIC represents something of an academic exercise because there is no specific treatment for the condition. Scoring systems that assess the severity of DIC are most useful for distinguishing DIC from other causes of coagulopathy (e.g., hypothermia, dilution, and drug effects) [see Table 2]. Heparin, antifibrinolytic agents, and antithrombotics

Table 2 Coagulopathy (DIC) Score

Score	INR (s)	aPTT (s)	Platelets (1,000/ μ L)	Fibrinogen (mg/dL)	D-Dimer (ng/mL)
0	< 1.2	< 34	> 150	> 200	< 1,000
1	> 1.2	> 34	< 150	< 200	< 2,000
2	> 1.4	> 39	< 100	< 150	< 4,000
3	> 1.6	> 54	< 60	< 100	> 4,000

aPTT = activated partial thromboplastin time; DIC = disseminated intravascular coagulopathy; INR = international normalized ratio.

(e.g., antithrombin and protein C) have been used. Despite improvements in laboratory measures with some of these agents, they do not appear to improve survival. One interpretation of the PROWESS trial²⁷ that evaluated drotrecogin alfa (recombinant activated protein C) as treatment for sepsis is that the observed improvement in survival resulted from containment of intravascular coagulation. However, the mortality benefit in that study has not been replicated in other trials and may not apply to patients undergoing operations. Currently, the most appropriate treatment of severe DIC is removal of the clotting stimulus and aggressive transfusion to restore blood loss and clotting factor deficits. The high mortality associated with severe DIC probably relates more to the underlying pathology than to the hematologic derangement per se.

An increased INR with a prolonged aPTT may also be caused by various isolated factor deficiencies of the common pathway. Congenital deficiencies of factors X and V and prothrombin are very rare. Acquired factor V deficiencies have been observed in patients with autoimmune disorders. Acquired hypoprothrombinemia has been documented in a small percentage of patients with lupus anticoagulants who exhibit abnormal bleeding. Factor X deficiencies have been noted in patients with amyloidosis.

Several anticoagulant medications can affect both the INR and the aPTT. Patients receiving large doses of unfractionated heparin may have a prolonged INR, depending on the specific reagents used in the test, and the related oral anti-Xa inhibitors (e.g., rivaroxaban) may also prolong both the INR and the aPTT.²⁸ The oral direct thrombin inhibitors typically prolong the aPTT but can also affect the INR. Stabilized warfarin therapy will increase both the INR and the aPTT. Several rodenticides in the vitamin K antagonist class with warfarin (e.g., brodifacoum) exert the same effect; however, because they have a considerably longer half-life than warfarin, the reversal of the anticoagulation effect with vitamin K or FFP may be correspondingly longer.²⁹ Animal venoms may also increase the INR and the aPTT.

Approach to the Patient with Anemia

Anemia is common among hospitalized surgical patients. In large prospective cohort studies, the average hemoglobin level in surgical ICU patients was 11.0 g/dL,³⁰ and 55% of surgical ICU patients received transfusions.³¹ Anemia results from at least three factors: (1) blood loss related to the primary

condition or to the operation, (2) serial blood draws (totaling, on average, approximately 40 mL/day in the ICU),³⁰ and (3) diminished erythropoiesis related to the primary illness.

Treatment of anemia has evolved over the past few decades. Cellular transfusions have long been a common, available

means to treat anemia in the perioperative and critical care setting, but recognition in the 1980s that blood products were transmitting fatal viral infections changed the risk-benefit analysis. The blood-banking community in the United States and most developed countries adapted and systematically reduced the risk of transmission of the most likely infectious agents by restricting the eligible donor pool and routinely testing blood products for serologic and nucleic acid evidence of pathogens.³² Currently, the possibility that an unpredictable new pathogen might emerge, such as a novel or mutated virus, is thought to pose a greater risk to the safety of the blood supply than such recognized pathogens as HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV). These latter viruses are now so rarely transmitted in developed countries that the incidence of transfusion-related infection is difficult to quantify.

Transfusion of allogeneic blood products has also been associated with significant dysfunction of the immune system and inflammatory processes. These immunomodulatory effects are presumably much more frequent than rare cases of viral transmission, but it is not clear whether they are causally related to poorer outcomes [see Discussion, Mechanism and Significance of Transfusion-Related Immunomodulation, *below*]. Furthermore, transfusion also may not augment oxygen delivery as assumed as a result of a variety of changes that occur with red cell storage.

Moreover, randomized trials comparing a restrictive RBC transfusion protocol (hemoglobin concentration maintained at 7.0 to 9.0 g/dL) with a more liberal protocol (hemoglobin maintained at 10.0 to 12.0 g/dL) for critically ill patients have not demonstrated harm with the restrictive approach.³³ In fact, as suggested by the Transfusion Requirements in Critical Care (TRICC) study, the restrictive approach may even improve survival for younger or less severely ill patients.³⁴

Thus, for a variety of reasons, the conventional wisdom is to try to limit blood transfusions when possible. The decision whether to transfuse should be based on the patient's current and predicted need for additional oxygen-carrying capacity [see *Figure 1*]. First, it is important to determine whether significant hypovolemia or active bleeding is present. In such patients, liberal transfusion is indicated as a means of increasing intravascular volume and preventing the development of profound deficits in oxygen-carrying capacity [see Approach to the Patient with Massive Hemorrhage, *above*].

In a hemodynamically stable but critically ill patient without evidence of active hemorrhage, it is appropriate to take a more restrictive approach and administer transfusion only when the hemoglobin concentration is less than 7.0 g/dL (hematocrit 21%). Less acutely ill patients can even be followed for hemoglobin concentrations below 7.0 g/dL, especially if they are asymptomatic and at minimal risk for hemorrhage. In the absence of transfusion, iron supplementation should be considered, particularly for menstruating women. There is no specific hemoglobin concentration or hematocrit (i.e., transfusion trigger) at which all patients should receive transfusions.

The above approach should apply to most patients, but there are two groups for whom a more aggressive RBC transfusion policy should be considered. Although opinion is divided, patients who have acute coronary artery ischemic syndromes and those with acute neurologic conditions may

benefit from a more liberal transfusion strategy. To date, relatively few such patients have been included in the randomized trials on this topic.

Acute Coronary Artery Ischemic Syndromes

Currently, there is no consensus regarding the most appropriate transfusion strategy for patients with acute coronary artery ischemic syndromes, such as active myocardial infarction and unstable angina. The results of observational studies have been mixed,^{35,36} and no clinical trial has yet addressed this specific subgroup of patients. Some distinction should be drawn between patients who have acute coronary artery ischemic syndromes and those who merely have a history of coronary artery or other atherosclerotic disease. Although the TRICC trial did not enrol patients admitted after a routine cardiac surgical procedure,³⁴ it included enough patients with cardiovascular disease to allow a sizable subgroup analysis.³⁷ This post hoc analysis suggested that in patients with cardiovascular disease as a primary diagnosis or an important comorbid condition, survival was essentially the same regardless of whether a liberal transfusion protocol or a restrictive one was followed. In patients with confirmed ischemic heart disease, however, a nonsignificant decrease in survival was noted, generating some concern that adverse cardiovascular events (e.g., myocardial infarction and stroke) might increase in frequency at lower hemoglobin levels. Consequently, a target hemoglobin of 10 g/dL is generally considered acceptable for patients with acute coronary artery ischemic syndromes or significant coronary artery disease.

Neurologic Conditions

Some have argued that just as the heart may be sensitive to decreases in oxygen-carrying capacity, the injured central nervous system may be vulnerable to further damage from anemia because anemia may limit the delivery of oxygen to damaged tissue. According to this view, patients with traumatic brain injury, stroke, or spinal cord injury may be vulnerable to anemia-related damage; however, as yet, the clinical evidence—mostly from observational studies with significant methodological weaknesses—is insufficient either to support or to refute liberal transfusion of such patients.³⁸

Symptomatic Anemia

An additional consideration in the decision to transfuse blood is the oxygen-carrying capacity that is necessary to prevent patient fatigue or discomfort. Typical symptoms of anemia include lightheadedness, tachycardia, and tachypnea either during activity or at rest. Clearly, some degree of tachycardia is to be expected in any patient who has undergone a major operation or sustained a serious injury. The key judgment to make in deciding whether to treat symptomatic anemia with transfusion is whether the anemia is truly compromising the patient's health or recovery. It is not always easy, however, to determine whether symptoms or signs attributed to anemia will actually improve as a result of transfusion. For example, a liberal transfusion approach does not appear to lead to earlier discontinuation of mechanical ventilation.³⁹ A major randomized trial that is near completion, the Functional Outcomes in Cardiovascular Patients Undergoing

Figure 1 Algorithm depicting the decision-making process for transfusion in anemic patients.

Surgical hip fracture repair (FOCUS) study, is addressing the issue of functional recovery. Its primary aim is to determine whether liberal transfusion improves walking ability among anemic patients with a history of cardiovascular disease who undergo operative repair of a hip fracture.⁴⁰

Observation of Anemia

Although it is now standard practice to observe patients with hemoglobin concentrations of 6 to 7 g/dL, data suggest that the benefits of transfusion probably outweigh the risks below this level.

For all patients, if the hemoglobin level drops low enough, cellular metabolism cannot be sustained and death becomes a certainty. Followers of certain religious faiths who decline blood transfusion even when death is the probable or certain consequence have provided valuable observational data on the effects of severe anemia that would otherwise be unethical to obtain. Such cases have challenged surgeons and intensive care physicians to find techniques for supporting life at extremely low hemoglobin concentrations and have helped define the limits beyond which anemia may be fatal. Reviews of patients who have refused transfusion suggest that a hemoglobin below 5 g/dL results in substantial increases in mortality, especially in elderly persons and patients with cardiovascular disease.⁴¹

When RBC transfusion is not possible (whether because the patient declines transfusion or because compatible blood is unavailable), a number of temporizing measures can be

used. First, steps should be taken to minimize additional iatrogenic blood loss. Laboratory tests should be restricted to those that are most likely to benefit the patient and should be conducted with the smallest amount of blood possible (e.g., pediatric specimen tubes). Nonemergency operations that are likely to involve appreciable blood loss should be postponed if possible. Second, any impediments to native erythropoiesis should be removed: iron should be supplemented (orally if possible), and the administration of recombinant erythropoietin should be considered. Third, 100% oxygen should be administered because oxygen dissolved in plasma contributes a significant proportion of oxygen delivery at very low hemoglobin levels. Fourth, in extreme cases, consideration should be given to decreasing oxygen demand. Because the mechanical work of respiration itself becomes a significant contributor to oxygen demand in severely anemic patients, mechanical ventilation and even neuromuscular blocking agents should be considered to reduce oxygen demand from skeletal muscle. The metabolic rate can be further reduced by inducing hypothermia.

For decades, efforts have been in progress to augment oxygen-carrying capacity using RBC substitutes. Various different substitutes have been evaluated, some of which remain under investigation. None have been approved for routine use by the US Food and Drug Administration (FDA), largely because of significant adverse effects. The main categories of substitutes are those based on hemoglobin and those based on perfluorocarbons. Unmodified, acellular hemoglobin is nephrotoxic, so hemoglobin-based blood substitutes involve

either attempts to modify the hemoglobin molecule or encapsulate hemoglobin within synthetic membranes. Even with such modifications, however, these substitutes appear to increase the risk of death and myocardial infarction.^{42,43} Perfluorocarbon-based substitutes have attempted to take advantage of the high solubility of oxygen in these liquids, but their development has been impeded by practical hurdles in their

production and storage as well as adverse effects with their use.⁴⁴ Thus, although blood substitutes promise a number of advantages (increased shelf life, availability that is not limited by donor supply, and reduced or eliminated risk of incompatibility reactions and pathogen transmission), the extent to which they will ever be a suitable treatment for anemia in surgical patients is unclear.

Discussion

Mechanics of Hemostasis

Hemostasis is the term for the process by which cellular and plasma components interact in response to vessel injury to maintain vascular integrity and promote wound healing. The initial response to vascular injury (primary hemostasis) involves the recruitment and activation of platelets, which then adhere to the site of injury. Subsequently, plasma proteins, in concert with cellular components, begin to generate thrombin, which causes further activation of platelets and converts fibrinogen to fibrin monomers that polymerize into a fibrin clot (secondary hemostasis). The final step is the release of plasminogen activators that induce clot lysis and tissue repair.

The cellular components of hemostasis include endothelium, subendothelial cells and substrate, white blood cells (WBCs), RBCs, and platelets. The plasma components include a number of pro- and anticoagulant proteins that, once activated, can accelerate or downregulate thrombin formation or clot lysis to facilitate wound healing. In normal individuals, these hemostatic components are in a regulatory balance; thus, any abnormality involving one or more of these components can result in a pathologic state, whether of uncontrolled clot formation (thrombosis) or of excessive bleeding (hemorrhage). These pathologies can result from either hereditary or acquired causes.

CELLULAR COMPONENTS

Endothelium and Subendothelial Tissue

The endothelium has both procoagulant and anticoagulant properties. At baseline, in its normal, undamaged state, the endothelial surface is covered with endogenous antithrombins (antithrombin III, heparan sulfate, dermatan sulfate, and others) that protect against pathologic coagulation, thus providing a barrier between prothrombotic factors in the plasma and thrombogenic subendothelial factors. However, when vascular injury occurs, the endothelium and subendothelial tissues serve as a nidus for recruitment, adhesion, and aggregation of platelets. Disruption of the endothelium exposes collagen fibrils, to which platelets adhere, and tissue factor (TF), which serves as an integral, potent clotting stimulus [see Procoagulants, *below*]. TF is pervasive on the cell surfaces of subendothelial tissue and especially concentrated on such tissue as vascular adventitia, cerebral cortex, lung parenchyma, visceral organ capsules, and epidermis.⁴⁵ Damaged or activated endothelial cells express adhesion molecule receptors (E-selectin and P-selectin), and release of vWF from

the Weibel-Palade bodies of endothelial cells causes platelets to adhere to their surface. The presence of interleukin-1 β (IL-1 β), tissue necrosis factor (TNF), interferon gamma, and thrombin also promotes expression of TF on the endothelium.^{46,47} TF activates factors X and VII, and these activated factors generate additional thrombin, which increases both fibrin formation and platelet aggregation.

The endothelium also acts in numerous ways to downregulate coagulation.⁴⁸ Heparan sulfate and thrombomodulin are both downregulators of thrombin formation. In the presence of thrombin, the endothelium responds by expressing or releasing (1) membrane-bound thrombomodulin, which forms a complex with thrombin to activate protein C; (2) endothelium-derived relaxing factor (i.e., nitric oxide⁴⁹) and prostacyclin, which have vasodilating and platelet aggregation-inhibiting effects, respectively; and (3) tissue plasminogen activator (t-PA) or urokinase-type plasminogen activator (u-PA), either of which converts the zymogen plasminogen to its active form, plasmin, that degrades fibrin and fibrinogen.^{47,50} Heparan sulfate, on the endothelium wall, forms a complex with plasma antithrombin to neutralize thrombin. The endothelium is also the source of tissue factor pathway inhibitor (TFPI), which downregulates TF-VIIa-Xa complexes.

Erythrocytes and Leukocytes

The nonplatelet cellular components of blood play indirect roles in hemostasis. RBCs contain thromboplastins that are potent stimulators of various procoagulant proteins. In addition, in the setting of laminar flow, a sufficient concentration of RBCs within the bloodstream (i.e., the hematocrit) assists in primary hemostasis by physically forcing the platelets toward the endothelial surfaces. When the RBC count is low enough, there is a reduction in this force, which results in inadequate endothelium-platelet interaction and subsequently a bleeding diathesis.

Leukocytes have several functions in the hemostatic process. The interaction between the adhesion molecules expressed on both leukocytes and endothelium results in cytokine production, initiation of inflammatory responses, and degradation of extracellular matrix to facilitate tissue healing. In the presence of thrombin and other stimuli, monocytes express TF, potentiating coagulation. Neutrophils and activated monocytes bind to stimulated platelets and endothelial cells that express P-selectin. Adhesion and rolling of neutrophils, mediated by fibrinogen and selectins on the endothelium, appear to help restore vessel integrity but may

also lead to inflammatory responses.^{51,52} Lymphocytes also adhere to endothelium via adhesion molecule receptors and appear to be responsible for cytokine production and inflammatory responses.

Platelets

Platelets facilitate hemostasis and subsequent fibrin formation both by generating the initial platelet plug and by providing a phospholipid surface on which the activation of coagulation factors is localized. Activation of platelets by agonists such as adenosine triphosphate (ATP), ADP, epinephrine, thromboxane A₂, collagen, and thrombin causes platelets to undergo morphologic changes and degranulation. Degranulation releases procoagulants (e.g., thrombospondin, vWF, fibrinogen, ADP, ATP, and serotonin) that promote further platelet adhesion and aggregation and surface expression of P-selectin, which induces cellular adhesion. Platelet degranulation also results in the release of β -thromboglobulin, platelet factor 4 (which has antiheparin properties), various growth factors, and calcium, as well as the formation of platelet microparticles. Plasminogen activator inhibitor-1 (PAI-1) released from degranulated platelets neutralizes the fibrinolytic pathway by forming a complex with t-PA.

On exposure to vascular injury, platelets adhere to the exposed endothelium via binding of vWF to the GPIb-IX-V complex.⁵³ Conformational changes in the GPIIb-IIIa complex on the activated platelet surface enhance fibrinogen binding, which results in platelet-to-platelet aggregation and complex morphologic changes. The end result of these changes is a platelet plug with such dense adherence of platelets and such dramatic changes in platelet shape that, on electron microscopy, each platelet resembles a piece within a three-dimensional jigsaw puzzle. The phospholipid surface of the membranes of activated platelets then anchors activated IXa-VIIIa and Xa-Va complexes, thereby localizing thrombin generation.⁵⁴

PLASMA COMPONENTS

Procoagulants

In primary hemostasis, circulating plasma vWF—in addition to the vWF secreted by endothelial cells in response to injury—facilitates adhesion of platelets to the endothelium. Plasma vWF also serves as the carrier protein for factor VIII, preventing its neutralization by the protein C regulatory pathway.

Secondary hemostasis involves numerous plasma components. Traditional diagrams of the coagulation cascade depict two distinct pathways, the intrinsic and extrinsic pathways, that join in a final common pathway. The historical reason for depicting the coagulation cascade this way is to emphasize differences between the aPTT test (which is prolonged in the absence of sufficient quantities of components in the intrinsic pathway: factor XII, prekallikrein, and high-molecular-weight kininogen) and the INR (which measures clotting time in response to the extrinsic stimulus, TF). In vivo, however, the primary stimulus for secondary hemostasis is the exposure of TF (i.e., the extrinsic pathway), and the thrombin generated from this process activates factor VIII, effectively bypassing the initial steps in the intrinsic pathway. Accordingly, our focus is not on the standard view of intrinsic and extrinsic

pathways but rather on the different roles contact factors (part of the intrinsic cascade) and TF play in coagulation.

The main role of the contact factors (factor XII, prekallikrein, and high-molecular-weight kininogen) appears to be in downregulation of coagulation rather than the generation of thrombin. Even in patients completely lacking these factors, who have a markedly prolonged aPTT, abnormal bleeding does not occur. However, the contact factors activate the bradykinin (BK) pathway, which exerts profibrinolytic effects by stimulating endothelial release of plasminogen activators. It also stimulates endothelial production of nitric oxide and prostacyclin, which play vital regulatory roles in vasodilation and regulation of platelet activation.⁵⁵

The key initiator of plasma procoagulant formation is the expression of TF on cell surfaces.^{46,56} TF activates factor VII and binds with it to form the TF-VIIa complex, which activates factors X and IX. Factor Xa enhances its own production by activating factor IX, which in turn converts more factor X to Xa. Factor Xa also produces minimal amounts of thrombin by cleaving the prothrombin molecule. The thrombin generated from this process cleaves the coagulation cofactors V and VIII to enhance production of the factor complexes IX-VIIIa (intrinsic tenase) and Xa-Va (prothrombinase), which dramatically catalyzes conversion of prothrombin to thrombin [see Figure 2].⁵⁷

Thrombin has numerous effects, including pro- and antithrombotic functions. Its procoagulant properties include cleaving fibrinogen, activating the coagulation cofactors V and VIII, inducing platelet aggregation, inducing expression of TF on cell surfaces, and activating factor XIII. In cleaving fibrinogen, thrombin causes the release of fibrinopeptides A and B (fibrin monomer). The fibrin monomer undergoes conformational changes that expose the α and β chains of the molecule, which then polymerize with other fibrin monomers to form a fibrin mesh. Activated factor XIII cross-links the polymerized fibrin (between the α chains and the γ chains) to stabilize the fibrin clot and delay fibrinolysis.

Fibrin(ogen)olysis

Plasminogen is the primary fibrinolytic zymogen that circulates in plasma. In the presence of t-PA or u-PA (released from the endothelium), plasminogen is converted to the active form, plasmin. Plasmin cleaves fibrin (or fibrinogen) between the molecule's D and E domains, causing the formation of X, Y, D, and E fragments from fibrinogen degradation, and D-dimers from polymerized fibrin degradation. The secondary function of the fibrinolytic pathway is the activation by u-PA of matrix metalloproteinases that degrade the extracellular matrix.⁵⁸

Endogenous Antithrombotic Factors

In persons with normal coagulation status, downregulation of hemostasis occurs simultaneously with the production of procoagulants (e.g., activated plasma factors, stimulated endothelium, and stimulated platelets). In addition to their procoagulant activity, both thrombin and contact factors stimulate downregulation of the coagulation process. Thrombin forms a complex with endothelium-bound thrombomodulin to activate protein C, which inhibits factors Va and VIIIa. The thrombin-thrombomodulin complex also regulates the fibrinolytic pathway by activating a circulating plasma protein

Figure 2 Schematic representation of the procoagulant pathways. aPC = activated protein C; AT = antithrombin; PC = protein C; PS = protein S; TAT = thrombin-antithrombin; TF = tissue factor; TFPI = tissue factor pathway inhibitor.

known as thrombin-activatable fibrinolysis inhibitor (TAFI), which appears to suppress conversion of plasminogen to plasmin.⁵⁹ Contact factors are known to be required for normal surface-dependent fibrinolysis, and there is some evidence that contact factor deficiencies can lead to thromboembolism. Another plasma protein responsible for regulation of fibrinolysis is α_2 -antiplasmin, which binds to circulating and bound plasmin to limit breakdown of fibrin.

Circulating downregulating proteins include antithrombin (a serine protease inhibitor of activated factors—especially factors IXa, Xa, and XIa—and thrombin⁴⁵), proteins C and S (regulators of factors VIIIa and Va⁶⁰), C1 inhibitor (a regulator of factor XIa), TFPI (a regulator of the TF-VIIa-Xa complex⁶¹), and α_2 -macroglobulin (a thrombin inhibitor—the primary thrombin inhibitor in neonates⁶²). Limitation of platelet activation occurs secondarily as a result of decreased levels of circulating agonists and endothelial release of prostacyclin [see Figure 2].

Bleeding Disorders

INHERITED COAGULOPATHIES

Numerous congenital abnormalities of the coagulation system have been identified. These include abnormalities of plasma proteins (e.g., hemophilia and vWD), platelet receptors (e.g., Glanzmann thrombasthenia and Bernard-Soulier syndrome), and endothelium (e.g., telangiectasia). Abnormalities can involve abnormal protein synthesis resulting in a dysfunctional coagulation protein (a “defect”) or decreased protein production (a “deficiency”).

Most of the coagulation defects associated with the endothelium are closely related to thrombosis or atherosclerosis. Defects or deficiencies of thrombomodulin, TFPI, and t-PA, albeit rare, are associated with thrombosis.^{63,64} Vascular defects (e.g., hemorrhagic telangiectasias) may carry an

increased risk of bleeding as a consequence of dysfunctional fibrinolysis, concomitant platelet dysfunction, or coagulation factor deficiencies.⁶⁵

Abnormalities of RBCs and WBCs may promote thrombosis (e.g., decreased blood flow from polycythemia vera, leukocytosis, and sickle cell anemia) but usually do not cause major bleeding unless there is an associated severe thrombocytopenia.

The most common heritable disease associated with bleeding is vWD, with some countries having a prevalence as high as 1 to 2%. This condition is characterized by a variety of qualitative and quantitative abnormalities of vWF. There are three main categories of vWD [see Table 3]: reduced concentration of normal vWF (type 1), dysfunctional vWF (type 2), and the absence of vWF altogether (type 3). Type 2 vWD is classified into four subtypes (A, B, M, and N) based on the nature of the dysfunction. Type 1 is most common, accounting for 70 to 80% of cases of vWD, and varies in severity, with most affected individuals manifesting only a mild bleeding tendency. Diagnosis of vWD is based on a combination of the patient history and laboratory parameters. Patients with vWD typically experience bleeding from the mucous membranes. Because the most prevalent forms of vWD are inherited in an autosomal dominant fashion, careful questioning typically reveals affected relatives. Laboratory tests to confirm the diagnosis and determine the subtype of vWD include vWF antigen tests, functional assays (e.g., the ristocetin cofactor assay), vWF multimer assays, ristocetin-induced platelet aggregation assays, platelet count, and factor VIII levels. The ratio of activity:antigen (ristocetin cofactor assay result relative to vWF antigen level) is typically approximately 1 for vWF type 1 vWD and less than 0.6 for type 2 vWD. Appropriate treatment depends on which type of vWD the patient has. Desmopressin is typically sufficient prophylaxis or treatment for patients with type I vWD but is not always effective, and tachyphylaxis can occur. vWF/factor VIII

Table 3 Classification and Management of von Willebrand Disease

Type of von Willebrand Disease	Pathology	Proportion among All Cases of vWD	Diagnostic Evaluation	Primary Treatment
1	Deficiency in the amount of vWF produced	70–80%	Decreased vWF Ag and vWF RCo	Desmopressin (vWF/factor VIII concentrate if unresponsive to desmopressin)
2A	Failure of mutant vWF to form appropriate multimers or increased proteolysis of mutant vWF	10%	Normal or decreased vWF Ag; vWF RCo substantially decreased; vWF MM with high- and high/medium-molecular-weight forms absent	vWF/factor VIII concentrate
2B	Increased binding of mutant vWF to platelet glycoprotein Ib receptor, resulting in decreased circulating vWF	5%	Similar to type 2A, but thrombocytopenia, increased RIPA (even with low dose of ristocetin), and increased vWF binding to normal platelets	vWF/factor VIII concentrate, platelet transfusion
2M	Abnormal vWF binding site for platelet glycoprotein Ib receptor, leading to decreased affinity between vWF and platelets	Rare	Normal or decreased vWF Ag; vWF RCo substantially decreased; vWF MM normal and decreased vWF binding to normal platelets	vWF/factor VIII concentrate
2N	Abnormal vWF binding site for factor VIII, leading to decreased circulating factor VIII levels	Rare	Normal vWF Ag, vWF RCo, and vWF MM; decreased factor VIII level and factor VIII binding to vWF	vWF/factor VIII concentrate
3	Complete absence of vWF	Very rare	Absent vWF Ag, vWF RCo, and vWF MM	vWF/factor VIII concentrate
Platelet type	Increased binding of vWF to mutant platelet glycoprotein Ib receptor, resulting in decreased circulating vWF	Rare	Similar to type 2B except that, as with normal individuals, vWF does not bind to normal platelets	Platelet transfusion

RIPA = ristocetin-induced platelet aggregation (not the same as vWF RCo); vWF = von Willebrand factor; vWF Ag = von Willebrand factor antigen test; vWF MM = von Willebrand factor multimer analysis; vWF RCo = von Willebrand factor ristocetin cofactor assay.

concentrate is necessary for patients with type 1 who are not responsive to desmopressin and for patients with types 2 and 3 who undergo operations or experience major bleeding. Desmopressin may be contraindicated for patients with type 2B vWD because it can exacerbate the thrombocytopenia that they typically experience.⁶⁶

There are rare inherited defects of the platelet surface, including Glanzmann thrombasthenia (a defect in the GPIIb-IIIa complex), Bernard-Soulier syndrome (a defect in the GPIb-IX complex), and Scott syndrome (a defect in the platelet's activated surface that promotes thrombin formation).⁶⁷ Intracellular platelet defects (storage pool diseases) are also rare but do occur; examples are gray platelet syndromes (e.g., alpha granule defects), Hermansky-Pudlak syndrome, dense granule defects, Wiskott-Aldrich syndrome, and various defects in intracellular production and signaling (involving defects of cyclooxygenase synthase and phospholipase C, respectively).

Numerous pathologic states are also associated with deficiencies or defects of plasma procoagulants. Hemophilias A, B, and C were previously discussed [*see Interpretation of Coagulation Parameters, Normal INR, Prolonged aPTT, above*]. Inherited deficiencies of the other coagulation factors are very rare. Factor XIII deficiencies result in delayed post-operative or posttraumatic bleeding. Congenital deficiencies

of factor V, factor VII, factor X, prothrombin, and fibrinogen may become apparent in the neonatal period (presenting, for example, as umbilical stump bleeding); later in life, they result in clinical presentations such as epistaxis, intracranial bleeding, GI bleeding, deep and superficial bruising, and menorrhagia.

Defects or deficiencies in the fibrinolytic pathway are also rare and are most commonly associated with thromboembolic events. α_2 -Antiplasmin deficiencies and primary fibrin(ogen)olysis are rare congenital coagulopathies with clinical presentations similar to those of factor deficiencies. In primary fibrin(ogen)olysis, failure of regulation of t-PA and u-PA leads to increases in circulating plasmin levels, which result in rapid degradation of clot and fibrinogen.^{68,69}

ACQUIRED COAGULOPATHIES

A wide range of clinical conditions may cause deficiencies of the primary, secondary, or fibrinolytic pathways. Acquired coagulopathies are very common, but most do not result in spontaneous bleeding.

As noted, coagulopathies related to the endothelium are primarily associated with thrombosis rather than bleeding. A number of disorders may cause vascular injury, including sickle cell anemia, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura.

Acquired platelet abnormalities, both qualitative (i.e., dysfunction) and quantitative (i.e., decreases in absolute numbers), are common occurrences. Many acquired thrombocytopathies are attributable to medications (e.g., aspirin, ibuprofen, other nonsteroidal antiinflammatory drugs, various antibiotics, certain antihistamines, and phenytoin). Newer classes of antiplatelet drugs function by inhibiting platelet receptors [see Interpretation of Coagulation Parameters, Normal INR, Normal aPTT, *above*].⁷⁰ Thrombocytopenia can be primary or secondary to a number of clinical conditions. Primary bone disorders (e.g., myelodysplastic or myelophthitic syndromes) and spontaneous bleeding may arise when platelet counts fall below 10,000/ μ L.

Thrombocytopenia can be associated with immune causes (e.g., immune thrombocytopenic purpura and heparin-induced thrombocytopenia) or such conditions as a deficiency in the plasma metalloproteinase ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13) (thrombotic thrombocytopenic purpura). Acquired platelet dysfunction (e.g., acquired vWD) that is not related to dietary or pharmacologic causes has been observed in patients with immune disorders or cancer.

Multifactorial coagulopathies are common as well. Patients with severe renal disease typically exhibit platelet dysfunction (from excessive amounts of uremic metabolites), factor deficiencies associated with impaired protein synthesis and protein loss (as with increased urinary excretion), or thrombocytopenia (from diminished thrombopoietin production).^{71,72} Patients with severe hepatic disease commonly have impairment of coagulation factor synthesis, increases in circulating levels of paraproteins, and splenic sequestration of platelets.

Massive cellular transfusion can dilute the levels of clotting factors if more than 10 packed RBC units are given within a short period without plasma supplementation. In addition, because RBC units contain citrate as an anticoagulant, massive transfusion can induce a coagulopathy from hypocalcemia. Immunologic reactions to ABO/Rh mismatches can induce immune-mediated hypercoagulation. Acquired multifactorial deficiencies associated with extracorporeal circuits (e.g., cardiopulmonary bypass, hemodialysis, and continuous venovenous dialysis) can arise as a consequence of hemodilution from circuit priming fluid or activation of procoagulants after exposure to thrombogenic surfaces. Thrombocytopenia can result from platelet destruction and activation caused by circuit membrane exposure or can be secondary to the presence of heparin antibody.

Animal venoms can be either pro- or antithrombotic. The majority of the poisonous snakes in the United States (rattlesnakes in particular) have venom that works by activating prothrombin, but cross-breeding has produced a number of new venoms with different hemostatic consequences. The clinical presentation of coagulopathies associated with snakebites generally mimics that of consumptive coagulopathies.⁷³

Drug-induced factor deficiencies are common, particularly as a result of anticoagulant therapy. The most commonly used anticoagulants are heparin and warfarin. Heparin does not cause a factor deficiency; rather, it accelerates production of antithrombin, which inhibits factor IXa, factor Xa, and thrombin, thereby prolonging clot formation. Warfarin reduces procoagulant potential by inhibiting vitamin K synthesis, thereby reducing carboxylation of factor VII, factor

IX, factor X, prothrombin, and proteins C and S. Newer drugs that may also cause factor deficiencies include direct thrombin inhibitors (e.g., lepirudin and bivalirudin⁷⁴) and fibrinogen-degrading drugs (e.g., anicrod⁷⁵).

Isolated acquired factor deficiencies are relatively rare. Clinically, they present in exactly the same way as inherited factor deficiencies, except that there is no history of earlier bleeding. In some cases, there is a secondary disease (e.g., lymphoma or an autoimmune disorder) that results in the development of antibody to a procoagulant (e.g., factor V, factor VIII, factor IX, vWF, prothrombin, or fibrinogen).

Disseminated Intravascular Coagulation

DIC is a complex coagulation process that involves massive activation of the coagulation system with deposition of fibrin in the microvasculature that causes the subsequent activation of the fibrinolytic pathway. The overwhelming microvascular fibrin deposition is the cause of both the activation of the fibrinolytic system (which promotes more bleeding) and eventually multiple organ dysfunction syndrome (MODS). The activation occurs at all levels, including platelets, endothelium, and pro- and anticoagulants. It is crucial to emphasize that DIC is an acquired disorder that occurs secondary to an underlying clinical event (e.g., child birth complicated by amniotic fluid embolism, severe gram-negative infection, shock, severe traumatic brain injury, polytrauma, severe burns, or cancer). As noted [see Interpretation of Coagulation Parameters, Increased INR, Prolonged aPTT, *above*], there is some controversy regarding the best approach to therapy, but there is no doubt that treating the underlying cause of DIC is paramount to patient recovery.

DIC is not always clinically evident: low-grade DIC may lack clinical symptoms altogether and manifest itself only through laboratory abnormalities, even when thrombin generation and fibrin deposition are occurring. In an attempt to facilitate recognition of DIC, the disorder has been divided into three phases, distinguished on the basis of clinical and laboratory evidence. In phase I DIC, there are no clinical symptoms, and the routine screening tests (i.e., INR, aPTT, fibrinogen level, and platelet count) are within normal limits.⁷⁶ Secondary testing (i.e., measurement of antithrombin, prothrombin fragment, thrombin-antithrombin complex, and soluble fibrin levels) may reveal subtle changes indicative of thrombin generation. In phase II DIC, there are usually clinical signs of bleeding around wounds, suture sites, IV sites, or venous puncture sites, and decreased function is noted in specific organs (e.g., lung, liver, and kidneys). The INR is increased, the aPTT is prolonged, and the fibrinogen level and platelet count are decreased. Other markers of thrombin generation and fibrinolysis (e.g., D-dimer level) show sizable elevations. In phase III DIC, MODS is observed, the INR and the aPTT are markedly increased, the fibrinogen level is markedly depressed, and the D-dimer level is dramatically increased. A peripheral blood smear shows large numbers of schistocytes, indicating RBC shearing from fibrin deposition.

The activation of the coagulation system seen in DIC appears to be primarily caused by TF. The brain, the placenta, and solid tumors are all rich sources of TF. Gram-negative endotoxins also induce TF expression. The exposure of TF on cellular surfaces causes activation of factors VII and

IX, which ultimately leads to thrombin generation. Circulating thrombin is rapidly cleared by antithrombin. Moreover, the coagulation pathway is downregulated by activated protein C and protein S. However, constant exposure of TF (as a result of underlying disorders) results in constant generation of thrombin, and these regulator proteins are rapidly consumed. TAFI and PAI also contribute to fibrin deposition by restricting fibrinolysis and subsequent fibrin degradation and clearance. Finally, it is likely that release of cytokines (e.g., IL-6, IL-10, and TNF) may play some role in causing the sequelae of DIC by modulating or activating the coagulation pathway.

Laboratory Assessment of Bleeding

Patients with massive or life-threatening hemorrhage should be treated presumptively and without a delay to obtain the results of laboratory tests [see Approach to the Patient with Massive Hemorrhage, *above*]. However, these tests serve an integral role in the diagnostic algorithm for patients with more modest bleeding. If the patient is not experiencing massive or life-threatening hemorrhage, blood samples for coagulation testing should be drawn before administering blood products or medication intended to promote coagulation. The CBC (including platelet count and differential count), the INR, and the aPTT tests should be the primary laboratory tests for differentiating coagulopathies [see Figure 3]. Technological advances have made it possible to perform these and other diagnostic laboratory tests outside the confines of the clinical laboratory (“near-care” or “point-of-care” testing). Whatever tests of coagulation are employed, it is important to recognize their limitations.

Several technical factors can influence the results of the INR and aPTT. These tests involve adding activators, phospholipids, and calcium to plasma in a test tube (or the equivalent) and determining the time to clot formation. Time to clot formation is a relative value in that it is compared with the time in a normal population, and each laboratory must periodically adjust the reference range accordingly. Poor sampling techniques (e.g., hemolysis, inadequately filled coagulation tubes, excessive tourniquet time, and clotted or activated samples) can influence the results. Hemolysis from poor phlebotomy technique can release thromboplastins from RBC membranes that initiate the coagulation process. An elevated hematocrit or inadequately filled specimen tube can prolong test results because the excess citrate chelates the calcium added in the assay. Hemolysis, jaundice, and lipemia can all interfere with the optical systems that modern instruments use to detect clot. In addition, factor VIII in particular is relatively labile, so failure to process and run coagulation samples expeditiously can prolong the aPTT.

Not all coagulation tests are functionally equivalent: different laboratory methods may yield differing results.⁷⁷ For most laboratories, coagulation reagents have been selected in such a way as to ensure that the tests are sensitive to factor VIII and IX deficiencies (i.e., diagnosis and monitoring of hemophilia) and the effects of warfarin and heparin. As a consequence, a normal aPTT in a patient with an abnormal INR may not exclude the possibility of common pathway deficiencies (e.g., deficiencies of factors X, V, and II), and most current methods of determining the INR and the aPTT

Figure 3 Algorithm depicting the use of coagulation parameters in assessment of coagulopathies. aPTT = activated partial thromboplastin time; DIC = disseminated intravascular coagulation; INR = international normalized ratio; vWD = von Willebrand disease.

do not detect low fibrinogen levels. In this chapter, we have assumed that the methods used with the INR and aPTT tests result in abnormalities when factor activity levels fall below 0.4 IU/mL.

Assessment of platelets also involves certain pitfalls. Platelet count and platelet function should be considered as completely independent metrics [see Figure 4]. Patients with congenital thrombocytopathies often have normal platelet counts; therefore, assessment of platelet function is required as well. Historically, the bleeding time has been used to assess platelet function. However, this test is grossly insensitive, yielding normal results in as many as 50% of patients with congenital thrombocytopathies.^{78,79} Numerous rapid tests of platelet function are currently available that can be used to screen for platelet defects; although the accuracy and clinical

Figure 4 Algorithm depicting the use of platelet count and platelet functional status in assessment of coagulopathies. MDS = myelodysplastic syndrome; vWD = von Willebrand disease.

utility of these tests have not been thoroughly evaluated, they can be considered in the diagnostic approach to the bleeding patient [see Table 4].

The role of point-of-care testing appears to be expanding. The activated clotting time (ACT) has been used in the setting of cardiopulmonary bypass to monitor anticoagulation when such high levels of unfractionated heparin are used that no clotting would occur with the aPTT. A newer class of tests, commonly referred to as thromboelastography, measure viscoelastic changes in whole blood as it clots. In this technique, a pin is suspended from a torsion wire into a cup containing blood. The cup rotates periodically, and, as clot forms and later lyses over time, the device detects changes in torque transmitted to the immersed pin. The most commonly reported device is the thromboelastograph (TEG, Haemoscope Corporation, Niles, IL), but other devices using related methods include the rotational thromboelastogram (ROTEM, TEM International GmbH, Munich, DE) and the Sonoclot (Sienco Inc, Arvada, CO). The TEG and ROTEM report similar parameters [see Figure 5], but the values are not directly comparable. Modifications of the basic sample cup allow users to isolate specific abnormalities. Although certain patterns may reflect specific abnormalities, software applications have made graphs easier to interpret. Although these methods lack specificity and clinical outcome studies are not yet available, graphically depicted abnormalities may lead to

Product (Manufacturer)	Method
PFA-100 (Dade Behring)	Measures time required to occlude aperture after exposure to platelet agonists (collagen/epinephrine and collagen/ADP) at shear rates
hemoSTATUS (Medtronic)	Measures modified activated clotting time with platelet-activating factor as the platelet agonist
Whole Blood Aggregometers (Chronolog Corporation)	Measures changes in impedance after addition of platelet agonist(s)
Ultra Analyzer (Accumetrics)	Used primarily for measuring the effect of platelet glycoprotein blockers (e.g., abciximab and eptifibatide), aspirin, or P2Y12 inhibitors
Platelet Works (Helena Laboratories)	Compares platelet counts before and after addition of agonists (collagen and ADP)
Impact Cone and Plate(let) Analyzer (Diamd)	Measures platelet aggregates after exposure of whole blood to shear forces in a spinning cone
Multipate function analyzer (Verum Diagnostica GmbH)	Measures changes in impedance after addition of platelet agonist with four-channel impedance technology
Thromboelastometry	TEG analyzer with platelet mapping protocol, CSA and ROTEM with platelet function assessment [see Laboratory Assessment of Bleeding, above]

ADP = adenosine diphosphate.

better directed therapy. The trauma surgery community in particular has generated enthusiasm for thromboelastography to allow real-time monitoring of coagulopathic acutely injured patients. The main strength of the test may be to identify hyperfibrinolysis in a more timely fashion than traditional laboratory methods do, assisting clinicians in selecting patients for antifibrinolytic therapy (e.g., ϵ -aminocaproic acid).

At present, there are no laboratory or ex vivo methods capable of directly measuring the physiologic properties of the endothelium. Indirect assessments of endothelial damage can be obtained by measuring levels of several laboratory parameters (e.g., vWF, the soluble cytokines endothelin-1 and E-selectin, and thrombomodulin), but such measurements have no clinical utility in the assessment of a bleeding patient.

Mechanism and Significance of Transfusion-Related Immunomodulation

Although a unit of packed RBCs is an exceedingly complex biologic substance, blood is used frequently and somewhat casually, compared with many pharmaceutical agents that have undergone extensive regulatory review. A unit of allogeneic transfused blood contains antigenic RBCs, WBCs, and

Figure 5 Schematic thromboelastogram (a), description of common thromboelastometry parameters (b), and illustration of selected abnormalities of coagulation (c). DIC = disseminated intravascular coagulation.

platelets; an array of antigenic or immunologically active substances in plasma (including both substances from donor plasma and substances that accumulate during storage); and, potentially, viral, bacterial, and parasitic pathogens. However, the specific transfusion-related factors that result in dysregulation of the innate or adaptive immune responses, as well as the clinical consequences of this immunomodulation, remain inadequately defined.

Interest in the immunosuppressive effect of blood transfusion stemmed in part from the observation by Opelz and colleagues in 1973 that recipients of cadaveric renal transplants experienced longer graft survival if they had undergone allogeneic blood transfusion before transplantation.⁸⁰ A number of different strategies for mitigating this immunosuppressive effect have been considered, including restrictive criteria for transfusion, administration of autologous blood products, and reduction of the quantity of donor leukocytes in units of blood. Buffy-coat reduction removes 70 to 80%

of donor leukocytes, but leukoreduction, typically through prestorage filtration techniques, removes more than 99.9% of donor leukocytes. Although leukoreduction has not been required by the FDA, it is required in Canada and several European countries and has been adopted by many blood banks in the United States, in part because it reduces the frequency of febrile transfusion reactions, cytomegalovirus transmission, and alloimmune platelet refractoriness.

Although donor leukocytes appear to be the most likely mediators of transfusion-related immunomodulation, donor erythrocytes or antibodies could also play a role. With increased storage time, donor erythrocytes develop a “storage lesion,” including morphologic changes that could impair their flow through the capillary microcirculation. A recent observational study of patients transfused in the setting of a cardiac operation found an association between older (i.e., greater than 14 days since donation) units of blood and increased postoperative complications and mortality.⁸¹

However, this study has been criticized for several methodologic issues, and many consider the issue unsettled. Transfusion-related acute lung injury (which some define very broadly to include underrecognized cases of immunomodulation) appears to be caused in some cases by donor antibodies to recipient leukocyte antigens. This has led some blood centers to exclude individuals likely to have such antibodies (e.g., previously pregnant women) from plasma donation.⁸²

A plethora of observational studies and some randomized trials have attempted to evaluate the role of blood transfusion in the recurrence of resected malignancies and postoperative infection. Most of the observational studies have compared the outcomes of transfused cohorts with those of nontransfused cohorts. The randomized trials, however, have mostly evaluated different kinds of blood transfusions against one

another (e.g., autologous versus allogeneic and leukoreduced versus nonleukoreduced). The literature is extensive, but many methodologic issues have been identified that limit the validity of the studies.⁸³ Accordingly, the evidence appears to be insufficient to establish a causal connection between allogeneic blood transfusion and either increased cancer recurrence or postoperative infection. Nonetheless, the heterogeneity of the study results and the finding of a major randomized trial, the TRICC trial, that a restrictive transfusion policy may improve survival in some patients continue to fuel debate over whether the avoidance or modification of allogeneic blood transfusion may improve patient outcomes.

Financial Disclosures: None Reported

5 POSTOPERATIVE MANAGEMENT OF THE HOSPITALIZED PATIENT

Deborah L. Marquardt, MD, FACS, Roger P. Tatum, MD, FACS, and Dana C. Lynge, MD, FACS

At the beginning of the modern era of surgery, operative procedures commonly took place in an operating theater, performed by plainclothes surgeons in aprons for audiences of students and other onlookers. Afterward, patients were typically cared for at home or in a hospital ward, with scarcely any monitoring and little to help them toward recovery besides their own strength and physiologic reserve. In the current era, surgery is a high-tech, rapid-paced field, with new knowledge and technological advances seemingly appearing around every corner. Many of these new discoveries have allowed surgeons to work more efficiently and safely, and as a result, a number of operations have now become same-day procedures. In addition, some very complex operations that were once thought to be impossible or to be associated with unacceptably high morbidity and mortality have now become feasible thanks to advances in surgical technique, anesthesia, postoperative management, and critical care. The focus of our discussion is on the postoperative considerations that have become essential for successful recovery from surgery.

Each patient is unique, and each patient's case deserves thoughtful attention; no two patients can be managed in exactly the same way. Nevertheless, certain basic categories of postoperative care apply to essentially all patients who undergo surgical procedures. Many of these categories are discussed in greater detail elsewhere in *ACS Surgery*. Our objective in this chapter is to provide a complete yet concise overview of each pertinent topic.

Disposition

The term disposition refers to the location and level of care and monitoring to which the patient is directed after the completion of the operative procedure. Although disposition is not often discussed as a topic in its own right, it is an essential consideration that takes into account many important factors. It may be classified into four general categories as follows:

1. Home or same-day surgery via the recovery room
2. The intensive care unit (ICU), with or without a stay in the recovery room
3. The surgical floor via the recovery room
4. The telemetry ward via the recovery room

The disposition category that is appropriate for a given patient is determined by considering the following four factors:

1. The patient's preoperative clinical status (including both the condition being treated and any comorbid conditions), as indicated by the history, the physical examination, and the input of other medical practitioners

2. The operative procedure to be performed
3. The course and duration of the operative procedure
4. The patient's clinical status at the completion of the procedure, as managed with the help of anesthesia colleagues

The initial phase of disposition planning begins preoperatively. After a full history has been obtained and a complete physical examination carried out, the procedure to be performed is decided on. This decision then initiates a discussion of the complexity and potential complications associated with the procedure, as well as of the concerns and special needs related to any comorbid conditions that may be present. If, as is often the case, the surgeon requires some assistance with planning the operation around the patient's other health problems, input from appropriate medical and surgical colleagues can be extremely helpful. Key factors to take into consideration include the potential complications related to the procedure and the urgency of their treatment; the level of monitoring the patient will require with respect to vital signs, neurologic examination, and telemetry; and the degree of care that will be necessary with respect to treatments, use of drains, and wound care. Relatively few published references describe specific criteria for the various disposition categories; however, most hospitals and surgery centers will have developed their own policies specifying a standard of care to be provided for each category.

SAME-DAY SURGERY

Same-day surgery is appropriate for patients who (1) have few or no comorbid medical conditions and (2) are undergoing a procedure that involves short-duration anesthesia or local anesthesia plus sedation and that carries a low likelihood of urgent complications. Operations commonly performed on a same-day basis include inguinal or umbilical hernia repair, simple laparoscopic cholecystectomy, breast biopsy, and small subcutaneous procedures.

The growth in the performance of minor and same-day procedures has led to the development of various types of short-stay units or wards. The level of care provided by a short-stay ward is generally equivalent to that provided by a regular nursing ward; however, the anticipated duration of care is substantially shorter, typically ranging from several hours to a maximum of 48 hours. Short-stay wards also undergo some modifications to facilitate the use of streamlined teaching protocols designed to prepare patients for home care. Many hospitals now have short-stay units, as do some independent surgery centers.

SURGICAL FLOOR

The vast majority of patients receive the postoperative care they require on the surgical floor (or regular nursing ward). Assessment of vital signs, control of pain, care of wounds, management of tubes and drains, and monitoring of intake and output are addressed every 2 to 8 hours (depending on the variable). Assignment of the patient to the regular nursing ward presupposes that he or she is hemodynamically stable and does not need continuous monitoring.

The telemetry ward is a variant of the regular nursing ward. The care provided in the telemetry ward is generally equivalent to that provided on other floor wards except that patients undergo continuous cardiac monitoring. Patients commonly assigned to the telemetry ward after operation include (1) those with a known medical history of arrhythmias that may necessitate intervention, (2) those with intraoperative arrhythmias or other electrocardiographic (ECG) changes who are not believed to require ICU monitoring but who do need this form of cardiac follow-up, and (3) those making the transition from the ICU to a regular ward who are hemodynamically stable but who require ongoing follow-up of a cardiac issue.

INTENSIVE CARE UNIT

When early postoperative complications may necessitate urgent intervention and close observation is therefore essential, patients should be admitted to the ICU for postoperative care. Postoperative ICU admission may also be appropriate for patients who are clinically unstable after the procedure; these patients often require ongoing resuscitation, intravenous (IV) administration of vasoactive agents, ventilatory support, or continuous telemetry monitoring for dysrhythmias. In addition, admission to the ICU should be considered for patients in whom the complexity of drain management, wound care, or even pain control may necessitate frequent postoperative monitoring that is not available on a regular nursing ward. At present, there is no single set of accepted guidelines directing ICU admission. There are, however, published sources that can provide some guidance. For example, a 2003 article supplied recommendations for the various services to be provided by differing levels of ICUs.¹ Published recommendations of this sort may be adopted or modified by individual hospitals and surgery centers as necessary.

Care Orders

Nurses and other ancillary personnel provide the bulk of the care received by patients after a surgical procedure; accordingly, it is essential that they receive clear and ample instructions to guide their work. Such instructions generally take the form of specific postoperative orders directed to each ancillary service. Services for which such orders may be appropriate include nursing, respiratory therapy, physical therapy (PT), occupational therapy (OT), and diet and nutrition. In what follows, we briefly outline some of the common tasks that require orders to be directed toward these services.

NASOGASTRIC TUBES

Nasogastric (NG) tubes are commonly placed after gastrointestinal (GI) operations, most frequently for drainage of

gastric secretions when an ileus is anticipated or offloading of the upper GI tract when a fresh anastomosis is located close by. Although NG tubes have often been placed routinely after abdominal surgery, the current literature cites a number of reasons why routine use is inadvisable and selective use is preferable. For example, significantly earlier return of bowel function, a trend toward fewer pulmonary complications, and enhanced patient comfort and decreased nausea are reported when NG tubes are not routinely placed or when they are removed within 24 hours after operation.²

When postoperative placement of an NG tube is considered appropriate, an order from a physician is required, along with direction regarding the method of drainage. Sometimes NG tubes are placed to low continuous suction; more often, however, they are placed to low intermittent suction to eliminate the chance of continuous suction against a visceral wall and to promote generalized drainage. If large volumes of secretions are not expected, continuous gravity may be used instead of suction. A key concern with NG tubes is maintenance of the patency of both the main port and the sump port. Should either port become blocked, the tube will be rendered ineffective. This concern should be discussed with the nursing staff. At times, it may be necessary to issue specific orders to ensure that this concern is appropriately addressed. As a rule, surgical nurses are well acquainted with tube maintenance; however, if thick secretions are expected, orders for routine flushing may be indicated. When the tube is no longer indicated, its removal may be ordered.

URINARY CATHETERS

Urinary catheters can serve a large variety of purposes. In the setting of bladder or genitourinary surgery, they are often employed to decompress the system so that it will heal more readily. After general surgical procedures—and many other surgical procedures as well—they are used to provide accurate measurements of volume output and thus, indirectly, to give some indication of the patient's overall volume and resuscitation status. Furthermore, after many procedures, patients initially find it extremely difficult or impossible to mobilize for urination, and a urinary catheter may be quite helpful during this time.

Their utility and importance notwithstanding, urinary catheters are associated with the development of nosocomial urinary tract infections (UTIs). As many as 40% of all hospital infections are UTIs, and 80 to 90% of these UTIs are associated with urinary catheters [see Postoperative Complications, *below*]. Accordingly, when catheterization is no longer deemed necessary, prompt removal is indicated. As a rule, orders specifically pertaining to urinary catheter care are few, typically including gravity drainage, flushing to maintain patency (if warranted), and removal when appropriate. At times, irrigation is employed after urologic procedures or for the management of certain infectious agents.

OXYGEN THERAPY

Supplemental administration of oxygen is often necessary after a surgical procedure. Common indicators of a need for postoperative oxygen supplementation include shallow breathing and pain, atelectasis, operative manipulation in the chest cavity, and postoperative impairment of breathing mechanics. Because supplemental oxygen is considered a

medication, a physician's order is required before it can be administered. In many cases, oxygen supplementation is ordered on an as-needed basis with the aim of enabling the patient to meet specific peripheral oxygen saturation criteria. In other cases, it is ordered routinely in the setting of known preoperative patient oxygen use.

An important factor to keep in mind is that oxygen supplementation protocols may vary from one nursing unit to another. Different units may place different limitations on the amount of supplemental oxygen permitted, depending on their specific monitoring and safety guidelines. Another important factor is that patients with known obstructive pulmonary disease and carbon dioxide retention are at increased risk for respiratory depression with hyperoxygenation; accordingly, particular care should be exercised in ordering supplemental oxygen for these patients.

DRAINS

Drains and tubes are placed in a wide variety of locations for a number of different purposes—in particular, drainage of purulent materials, serum, or blood from body cavities. Several types are commonly used, including soft gravity drains (e.g., Penrose), closed-suction drains (e.g., Hemovac, Jackson-Pratt, and Blake), and sump drains, which draw air into one lumen and extract fluid via a companion lumen. Traditionally, surgeons have often made the decision to place a drain on the basis of their surgical training and practice habits rather than of any firm evidence that drainage is warranted. Multiple randomized clinical trials have now demonstrated that routine use of drains after elective operations—including appendectomies and colorectal, hepatic, thyroid, and parathyroid procedures—does not prevent anastomotic and other complications (although it does reduce seroma formation). Consequently, it is recommended that drains, like NG tubes, be employed selectively.³⁻⁵ Once a drain is in place, specific orders must be issued for its maintenance. These include use of gravity or suction (and the means by which suction is to be provided if ordered), management and measurement of output, stripping, and care around the drain exit site.

Biliary tract drains include T tubes, cholecystostomy tubes, percutaneous drains of the biliary tree, and nasobiliary drains. Daily site maintenance, flushing, and output recording are performed by the nursing staff. Most biliary tract drains are removed by the practitioner or other trained midlevel staff members.

T tubes are generally placed after operative exploration or repair of the common bile duct (CBD). The long phalanges are left within the CBD, and the long portion of the tube is brought out to the skin for drainage. The tube is left in place until the CBD is properly healing and there is evidence of adequate distal drainage (signaled by a decrease in external drainage of bile). Before the T tube is removed, a cholangiogram is recommended to document distal patency and rule out retained gallstones or leakage.⁶

Cholecystostomy tubes are placed percutaneously—typically under ultrasonographic guidance and with local anesthesia—to decompress the gallbladder. Generally, they are used either (1) when cholecystectomy cannot be performed, because concomitant medical problems make anesthesia or the stress of operation intolerable, or (2) when

the presence of severe inflammation leads the surgeon to conclude that dissection poses too high an operative risk. Particularly in the latter setting, delayed elective cholecystectomy may be appropriate; if so, the cholecystostomy tube may be removed at the time of the operation.

Nasobiliary tubes are placed endoscopically in the course of biliary endoscopy. They are used to decompress the CBD in some settings. They are usually placed to gravity and otherwise are managed in much the same way as NG tubes.⁷

WOUND CARE

The topic of wound care is a broad one. Here we focus on initial postoperative dressing care, traditional wet-to-dry dressings, and use of a vacuum-assisted closure device (e.g., VAC Abdominal Dressing System, Kinetic Concepts, Inc., San Antonio, TX). These and other components of wound care are discussed in more detail elsewhere.

Initial wound management after an operative procedure generally entails placement of a sterile dressing to cover the incision. The traditional recommendation has been to keep this dressing in place and dry for the first 48 hours after operation; because epithelialization is known to take place within approximately this period, the assumption is that this measure will reduce the risk of wound infection. Although most surgeons still follow this practice, especially in general surgical cases, supporting data from randomized clinical studies are lacking. In addition, several small studies that evaluated early showering with closed surgical incisions found no increases in the rate of infection or dehiscence.^{8,9} It should be kept in mind, however, that these small studies looked primarily at soft tissue and other minor skin incisions that did not involve fascia. Thus, even though the traditional approach to initial dressing management is not strongly supported, the data currently available are insufficient to indicate that it should be changed.

Wet-to-dry dressings are used in a variety of settings. In a surgical context, they are most often applied to a wound that cannot be closed primarily as a consequence of contamination or inability to approximate the skin edges. Wet-to-dry dressings provide a moist environment that promotes granulation and wound closure by secondary intention. Moreover, their removal and replacement cause débridement of excess exudate or unhealthy superficial tissue. Postoperative orders should specify the frequency of dressing changes and the solution used to provide dampness. For most clean open incisions, twice-daily dressing changes using normal saline solution represent the most common approach. If there is excess wound exudate to be débrided, dressing changes may be performed more frequently. If there is particular concern about wound contamination or superficial colonization of organisms, substitution of dilute Dakin solution for normal saline may be considered.

A new era of wound management arrived in the late 1990s with the introduction of negative-pressure wound therapy (NPWT). In NPWT, a vacuum-assisted wound closure device places the wound under subatmospheric pressure conditions, thereby encouraging blood flow, decreasing local wound edema and excess fluid (and consequently lowering bacterial counts and encouraging wound granulation), and increasing wound contraction.^{10,11} Since the first published

animal studies, NPWT has been successfully employed for a multitude of wound types, including complex traumatic and surgical wounds, skin graft sites, and decubitus wounds. Before vacuum-assisted closure is used, however, it is necessary to consider whether and to what extent the wound is contaminated, the proximity of the wound to viscera or vascular structures, and the potential ability of the patient to tolerate dressing changes. Wounds that are grossly contaminated or contain significant amounts of nonviable tissue probably are not well suited to an occlusive dressing system of this type given that frequent evaluation and possibly débridement may be needed to prevent ongoing tissue infection and death. Furthermore, the suction effect of the standard vacuum sponge may cause serious erosion of internal viscera or exposed major blood vessels. Some silicone-impregnated nonadherent sponges are available that may be suitable in this setting, but caution should be exercised in using them. Finally, because of the adherence of the sponge and the occlusive adhesive dressing, some patients may be unable to tolerate dressing changes without sedation or anesthesia.

Nutrition

The patient's nutritional status has a significant effect on postoperative morbidity and even mortality. After most operative procedures that do not involve the alimentary tract or the abdomen and do not affect swallowing and airway protection, the usual practice is to initiate the return to full patient-controlled oral nutrition as soon as the patient is fully awake. In these surgical settings, therefore, it is rarely necessary to discuss postoperative nutrition approaches to any great extent.

After procedures that do involve the alimentary tract or the abdomen, however, the situation is different. The traditional practice has been to institute a *nil per os* (NPO) policy, with or without NG drainage, after all abdominal or alimentary tract procedures until the return of bowel function, as evidenced by flatus or bowel movement, is confirmed. The routine application of this practice has been challenged, however, especially over the past 15 years. Data from prospective studies of high statistical power are lacking, but many smaller studies evaluating early return to enteral nutrition after alimentary tract procedures have yielded evidence tending to favor more routine use of enteral intake within 48 hours after such procedures.

Issues related to postoperative nutritional support are discussed further and in greater detail elsewhere.

NPO STATUS

In the setting of elective colorectal surgery, it is well-accepted practice to initiate a return to patient-controlled enteral-oral feeding within 24 to 48 hours after operation; this practice yields no increase in the incidence of postoperative complications (e.g., anastomotic leakage, wound and intra-abdominal infection, and pneumonia) or the length of hospital stay and, according to some reports, may even decrease them.¹² In the setting of upper GI surgery (specifically, gastric resection, total gastrectomy, and esophagectomy), the situation is less clear-cut. Traditional concerns—in particular, the need to avoid distention stress on gastric or gastrojejunal

anastomoses after gastric resection, the more tenuous nature of a esophagojejunostomy after total gastrectomy, and the delayed gastric conduit emptying, aspiration risk, and anastomotic stress seen after esophagectomy or resection—have led to the current practice of instituting NG drainage and placing the patient on NPO status postoperatively until evidence of the return of bowel function is apparent, as well as, in some cases, investigating the anastomosis for possible leakage by means of contrast fluoroscopy. There are no clinical trial data to support this approach. In fact, many surgeons routinely remove the NG tube within 24 hours after gastric resection and early feeding without incurring increased complications. However, there are also no clinical trial data indicating that the current approach is potentially ineffective or harmful. Consequently, traditional management methods after upper GI procedures still are often endorsed in the literature.^{13,14}

ENTERAL NUTRITION

Enteral nutrition may be delivered via several routes. Most patients who have undergone an operation are able to take in an adequate amount of calories orally. When they are unable to do so, whether because of altered mental status, impaired pulmonary function, or some other condition, the use of enteral feeding tubes may be indicated. In the acute setting, NG and nasojejunal feeding tubes are the types most commonly employed to deliver enteral solutions into the GI tract. Either type is appropriate for this purpose; the two types are equivalent overall as regards their ability to provide adequate nutrition, and there are no significant differences in outcome or complications. In cases where prolonged inability to take in adequate calories orally is expected, the use of an indwelling feeding tube, such as a gastrostomy or jejunostomy tube, may be indicated. These tubes must be placed either at the time of operation or subsequently via surgical or percutaneous means, and there is some potential for complications. The specific indications for the use of such tubes are patient derived; they are not routinely associated with the performance of specific procedures.

TOTAL PARENTERAL NUTRITION

Total parenteral nutrition (TPN) is a surrogate form of nutrition in which dextrose, amino acids, and lipids are delivered via a central venous catheter. It is a reliable method in that it delivers nutrients and calories regardless of whether the patient's gut is functioning. Nevertheless, multiple studies over the past 20 years have shown that when the patient has a functioning intestinal tract, enteral feeding is clearly preferable to TPN. Although the specific mechanisms are not fully understood, enteral nutrition is known to foster gut mucosal integrity, to support overall immune function, and to be associated with lower complication rates and shorter hospital stays. In contrast, TPN is known to be associated with altered immune function, an increased rate of infectious complications, and, in some studies, a higher incidence of anastomotic complications after GI surgery. Moreover, there are as yet no data to indicate that acute use of TPN during short periods of starvation benefits patients who are adequately nourished preoperatively. TPN may, however, be lifesaving in patients who are malnourished and who do not have functioning GI tracts (e.g., those with short gut syndrome, severe gut

dysmotility or malabsorption, mesenteric vascular insufficiency, bowel obstruction, high-output enteric fistulas, or bowel ischemia).¹⁵

CALORIC GOALS

Once a route of nutritional support has been decided on, overall goals for caloric and protein intake may be established on the basis of the patient's ideal body weight (IBW) and expected postoperative metabolic state. One approach is to rely on a general estimate; a commonly used formula is 25 kcal/kg IBW. Another approach is to calculate a basal energy requirement by using the Harris-Benedict equation. This calculation is separate from the calculation of protein needs. A daily protein intake goal may be calculated on the basis of the patient's estimated level of physical stress. A well-nourished unstressed person requires a protein intake of approximately 1.0 g/kg IBW/day. A seriously ill patient under ongoing severe physical stress, however, may require 2.0 g/kg IBW/day; in some settings (e.g., extensive burns), a protein intake as high as 3.0 g/kg IBW/day may be recommended. Once the patient's specific needs have been calculated, the amount and type of nutrient solution to be provided enterally or via TPN are determined. If the patient is on a full oral diet, a calorie count or recording of the percentage of items eaten at each meal or snack may be made by the nursing staff and used to estimate the patient's intake, with nutritional supplementation provided as needed.¹⁶

Patients who require assistance with nutritional intake should be monitored to determine whether the interventions being carried out are having the desired effect. The most common method of monitoring patients' nutritional status with nutritional supplementation is to measure the serum albumin and prealbumin (transthyretin) concentrations. Albumin has a half-life of approximately 14 to 20 days and thus serves as a marker of longer-term nutritional status. A value lower than 2.2 g/dL is generally considered to represent severe malnutrition, but even somewhat higher values (< 3.0 g/dL) have been associated with poorer outcomes after elective surgery. Although the serum albumin concentration is a commonly used marker, it is not always a reliable one. Because of albumin's relatively long half-life, the serum concentration does not reflect the patient's more recent nutritional status. In addition, the measured concentration can change quickly in response to the infusion of exogenous albumin or to the development of dehydration, sepsis, and liver disease despite adequate nutrition. Prealbumin is a separate serum protein that has a half-life of approximately 24 to 48 hours and thus can serve as a marker of current and more recent nutritional status. Like the albumin concentration, the prealbumin concentration can be affected by liver and renal disease. Overall, however, it is more immediately reliable in following the effects of nutritional intervention.

Fluid Management

IV fluids may be classified into two main categories: resuscitation and maintenance. Supplemental fluids constitute a third category.

RESUSCITATION FLUIDS

Resuscitation fluids maintain tissue perfusion in the setting of hypovolemia by restoring lost volume to the intravascular

space. They may be further classified into two subcategories: crystalloids and colloids.

Crystalloids

Crystalloid solutions are water-based solutions to which electrolytes (and, sometimes, organic molecules such as dextrose) have been added. The crystalloid solutions used for resuscitation are generally isotonic to blood plasma and include such common examples as 0.9% sodium chloride, lactated Ringer solution, and Plasma-Lyte (Baxter Healthcare, Round Lake, IL). The choice to use one solution over another is usually inconsequential, but there are a few notable exceptions. For example, in the setting of renal dysfunction, there is a risk of hyperkalemia when potassium-containing solutions such as lactated Ringer solution and Plasma-Lyte are used. As another example, the administration of large volumes of 0.9% sodium chloride, which has a pH of 5.0 and a chloride content of 154 mmol/L, can lead to hyperchloremic metabolic acidosis. Regardless of which crystalloid solution is used, large volumes may have to be infused to achieve a significant increase in the circulating intravascular volume. Only one third to one quarter (250 to 330 mL/L) of the fluid administered stays in the intravascular space; the rest migrates by osmosis into the interstitial tissues, producing edema and potential impairment of tissue perfusion (the latter is a theoretical consequence whose existence has not yet been directly demonstrated).¹⁷

Colloids

Colloid solutions are composed of microscopic particles dispersed in a second substance in such a way that they are suspended and do not separate by normal filtration. Colloids are derived from three main forms of semisynthetic molecules: gelatins, dextrans, and hydroxyethyl starches. All of the commonly used synthetic colloids are dissolved in crystalloid solution. Nonsynthetic colloids also exist, including human albumin solutions, fresh frozen plasma, plasma-protein fraction, and immunoglobulin solutions. Compared with crystalloid solutions, colloid solutions increase the circulating intravascular volume to a much greater degree per unit of volume infused. In this respect, the various colloids may be thought of as a single group; however, in practice, they are most often given selectively on the basis of secondary characteristics other than their volume-increasing action, such as effect on hemostasis, risk of allergic reaction, and cost.

Crystalloids versus Colloids

The debate over whether crystalloids or colloids are superior for resuscitation has been going on for at least 30 years. Although multiple randomized, controlled trials have compared the two types of solutions in a variety of settings, including sepsis, trauma, burns, and surgery, the evidence accumulated to date has not established that one is clearly better than the other in terms of overall outcome. Supporters of crystalloid resuscitation cite the risk of altered hemostasis, the increased likelihood of drug interactions and allergic reactions, the potential for volume overload, and the relatively high cost as factors arguing against the use of colloids. Supporters of colloid resuscitation cite the large volume of crystalloid needed to produce significant volume effects, the subsequent tissue edema, and the potential for impaired

tissue perfusion and oxygenation as factors arguing against the use of crystalloids. Current recommendations favor crystalloid for resuscitation, with colloid an acceptable substitute when its secondary effects are desired in specific situations.^{17,18}

MAINTENANCE FLUIDS

Maintenance fluids provide required daily amounts of free water and electrolytes (e.g., sodium, potassium, and chloride) to balance expected daily losses and maintain homeostasis. A basic rule of thumb used by many practitioners to calculate the infusion rate for maintenance IV fluids is the so-called 4, 2, 1 rule:

- 4 mL/kg/hr for the first 10 kg of body weight
- 2 mL/kg/hr for the next 10 kg of body weight and
- 1 mL/kg/hr for every 1 kg of body weight above 20 kg

Generally accepted maintenance requirements include 30 to 35 mL/kg/day for free water, 1.5 mEq/kg/day for chloride, 1 mEq/kg/day for sodium, and 1 mEq/kg/day for potassium. In the setting of starvation or poor oral intake, dextrose 5% is often added to maintenance fluids to inhibit muscle breakdown. In regular practice, however, these specific values are not commonly used; more often, a rough estimate is made of expected daily fluid requirements, and solutions are ordered in accordance with this estimate. Although this practice is unlikely to cause noticeable harm in the majority of postoperative patients, there are situations where inaccurate calculations can lead to dehydration and volume overload. Three studies from the early 2000s evaluated patients undergoing elective colorectal surgery with the aim of determining whether providing higher volumes of fluid perioperatively had an impact on outcome.^{19–21} In all three, the data supported the use of smaller fluid volumes perioperatively, which was shown to result in earlier return of gut function after operation, shorter hospital stays, and overall decreases in cardiopulmonary and tissue-healing complications.

SUPPLEMENTAL FLUIDS

Supplemental fluids are given to replace any ongoing fluid loss beyond what is expected to occur via insensible loss and excretion in urine and stool. They are most commonly required by patients with prolonged NG tube output, enterocutaneous fistulas, diarrhea, high-output ileostomies, or large open wounds associated with excessive insensible fluid loss. In each case, the amount of fluid lost daily should be calculated, and replacement fluid should be given in a quantity determined by this measurement (either as a whole or in part) and by the patient's overall intravascular volume status. The particular solution to be used depends on the characteristics of the fluid loss. The components and volume of the fluids produced in the GI tract are different at different sites [see *Table 1*].

Pain Control

The topic of postoperative pain control covers a broad spectrum of possible interventions that serve a wide range of purposes. The most obvious purpose is simply to relieve the suffering and stress associated with postoperative pain. Another is to improve the patient's overall postoperative

status. Bringing the patient closer to the baseline sensory state by reducing pain allows him or her to engage in activities that promote healing and prevent complications, including mobilization to help prevent deep vein thrombosis (DVT) and deep breathing and coughing to help prevent pneumonia. Common methods of pain relief include IV infusion of narcotics, epidural analgesia using local anesthetics with or without narcotics, oral administration of narcotics, and the use of nonnarcotic oral medications such as nonsteroidal antiinflammatory drugs (NSAIDs) and acetaminophen (see below). These and other issues related to postoperative pain control are discussed in greater detail elsewhere.

IV NARCOTIC ANALGESIA

IV narcotics may be administered either by the medical staff or, if patient-controlled analgesia (PCA) is feasible, by the patient. In most cases, with the exception of brief hospital stays (< 48 hours) and ICU settings where the patient may not be alert enough to manage a patient-controlled system, PCA is now generally considered preferable to as-needed nurse-administered IV narcotic analgesia. Numerous studies and reviews have shown that PCA is safe and is no more likely to cause side effects (e.g., oversedation, overdose, itching, and nausea) than nurse-administered IV narcotic analgesia is. In addition, the use of PCA improves patients' subjective perceptions of the efficacy of pain relief and the timeliness of drug administration.²²

EPIDURAL ANALGESIA

Epidural analgesia usually makes use of a local anesthetic (e.g., bupivacaine) with or without the addition of a narcotic (e.g., fentanyl). The anesthetic solution is instilled into the epidural space, bathing the nerve roots in a given region and thereby providing pain relief. Until the past decade or so, epidural analgesia was considered a more dangerous method of pain relief and was not routinely employed outside the ICU. With time and further observation has come the recognition that epidural analgesia is safe and effective for postoperative pain control in a routine floor setting if managed by the proper supporting team of physicians.

There has been some debate regarding whether epidural analgesia leads to earlier return of bowel function after GI surgery or reduces the incidence of pulmonary complications; at present, this debate remains unresolved. There is clear evidence, however, that patients subjectively experience less pain with epidural analgesia, both at rest and in the course of activities such as mobilization and coughing. Moreover, in patients who have sustained traumatic rib fractures, early use of epidural analgesia in place of IV narcotic analgesia has been shown to reduce the incidence of associated pneumonia and shorten the time for which mechanical ventilation is required.²³ Epidural analgesia does have certain drawbacks, including an increased incidence of orthostatic episodes and a need for more frequent adjustments of the medication dosage. Nevertheless, it can be highly effective and can be a reasonable option when judged appropriate by the anesthesiologist and agreed to by the patient.^{24,25}

ORAL ADMINISTRATION OF NARCOTICS

Oral administration of narcotics is one of the oldest methods of providing postoperative pain relief. Numerous

Table 1 Electrolyte Content and Rate of Production of Fluids Secreted in the Gastrointestinal Tract

Source of Secretion	Electrolyte Concentration (mEq/L)					Rate of Production (mL/day)
	Na ⁺	K ⁺	Cl ⁻	HCO ₃ ⁻	H ⁺	
Salivary glands	50	20	40	30		100–1,000
Stomach						
Basal	100	10	140		30	1,000
Stimulated	30	10	140		100	4,000
Bile	140	5	100	60		500–1,000
Pancreas	140	5	75	100		1,000
Duodenum	140	5	80			100–2,000
Ileum	140	5	70	50		100–2,000
Colon	60	70	15	30		

different narcotic agents are now available for use in this setting. When deciding which narcotic to prescribe, however, physicians typically do not select freely from the entire available range; rather, they tend to choose from a small subset of agents that they know well and are comfortable with. A key point to keep in mind is that in some formulations, narcotics are combined with other compounds (e.g., acetaminophen or aspirin), and these added medications can have side effects of their own if taken in excessively high doses. Such formulations may require more careful titration than narcotics alone would. Another key point is that many narcotics are available in both short-acting and long-acting versions. In patients who are experiencing substantial postoperative pain, a combination of long-acting agents and short-acting agents may yield more sustained and predictable pain relief than either type alone would.

Finally, for patients who have a history of chronic pain conditions and who regularly used pain medications preoperatively, the assistance of an acute pain service management team may be invaluable in treating pain postoperatively.

NSAIDS AND ACETAMINOPHEN

NSAIDs are available both by prescription and over the counter. They not only provide effective analgesia for pain from minor procedures but also may be a powerful adjunct to narcotics in more acute hospital settings. Their major disadvantages, which in some contexts are substantial enough to limit their use, include their propensity to cause gastric irritation and ulceration; their antiplatelet effects, which increase the tendency toward bleeding; and their potential nephrotoxic effects in some formulations. When employed in settings where these disadvantages are not considered to pose a high risk, NSAIDs can be a useful addition to narcotics, both by providing further pain relief and by reducing the required narcotic doses (and thus the incidence of narcotic-related side effects).

Like the NSAIDs, acetaminophen provides minor pain relief and is an antipyretic, but unlike the NSAIDs, it has no antiinflammatory effect. Acetaminophen also is often added to narcotic regimens or formulations to reduce the need for narcotics. Its greatest potential side effect is hepatic toxicity with excessive use. Accordingly, the dosage should be less

than 2 g/day in patients with normal hepatic function and even lower in those with impaired hepatic function. It is particularly important to keep these dose limits in mind when narcotic-acetaminophen combinations are prescribed on an as-needed basis; in this situation, safe dosage limits may well be exceeded if sufficient care is not taken.

Glycemic Control

Over the last decade, blood glucose control in the postoperative period has become a topic of great interest. Many studies, beginning with that of Van den Berghe and colleagues in 2001,²⁶ have found that strict glucose control reduces morbidity and mortality in critically ill surgical ICU patients. Although most of the data currently available are derived from ICU patients rather than from the surgical population as a whole, the principle of tight glycemic control has been generalized to apply to most postoperative patients.

The target glucose range has been the subject of debate, with most institutions using a range of 80 to 140 mg/dL. The ability to achieve this target range and the means of achieving it vary according to the level of nursing care that is provided. Options include continuous IV insulin infusion and combinations of subcutaneous injections that use various long- and short-acting insulin formulations. Episodes of hypoglycemia are an ever-present risk with tight glucose control; accordingly, the use of standard dosage regimens and careful monitoring are recommended to reduce the risk of such episodes.

The debate over the specifics of glycemic control notwithstanding, it is generally well accepted that this issue should be addressed in all patients who have undergone major operative procedures, regardless of whether they carry a preoperative diagnosis of diabetes mellitus.^{26,27}

Postoperative Complications

Numerous complications may arise in the postoperative period. Many of these are specific to particular operative procedures and hence are best discussed in connection with those procedures. Many others, however, may develop after virtually any operation and thus warrant a general discussion in this chapter (see below). Prompt discovery and treatment

of these latter complications rely heavily on a sufficiently high index of suspicion.

POSTOPERATIVE FEVER

Postoperative temperature elevations are quite common, occurring in nearly one third of patients after surgery. Only a relatively small number of these are actually caused by infection. Fevers that are caused by infections (e.g., pneumonias, wound infections, or UTIs) tend to reach higher temperatures ($> 38.5^{\circ}\text{C}$ [101.3°F]), usually are associated with moderate elevation of the white blood cell (WBC) count 3 or more days after operation, and typically extend over consecutive days. Noninfectious causes of postoperative fevers include components of the inflammatory response to surgical intervention, reabsorption of hematomas, and (possibly) atelectasis.²⁸

Beyond checking the WBC count, a shotgun approach to the workup of postoperative fever probably is not warranted. A focused approach based on well-directed questioning and a careful physical examination is more likely to obtain the highest diagnostic yield. Coughing, sputum production, and respiratory effort should be noted, and the lungs should be auscultated for rales. All incisions should be inspected for erythema and drainage, and current and recent IV sites should be checked for evidence of cellulitis. If a central line has been placed, particularly if it has been in place for several days, the possibility of a line infection should be considered. Patients who have undergone prolonged NG intubation may have sinusitis, which is most readily diagnosed through computed tomography (CT) of the sinuses. Further workup for fever may include, as indicated, chest x-ray, sputum cultures, urinalysis, blood cultures, or CT of the abdomen (after procedures involving laparotomy—especially bowel resections—where intra-abdominal abscess is a possible complication).

PNEUMONIA

Respiratory infections in the postoperative period are generally considered nosocomial pneumonias and, as such, are potentially serious complications. The estimated incidence of postoperative pneumonia varies significantly, with many estimates tending to run high. A 2001 study of more than 160,000 patients undergoing major noncardiac surgery provided what may be a reasonable overall figure, finding the incidence of postoperative pneumonia to be approximately 1.5%.²⁹ In the 2,466 patients with pneumonia, the 30-day mortality was 21%. Thoracic procedures, upper abdominal procedures, abdominal aortic aneurysm repair, peripheral vascular procedures, and neurosurgical procedures were all identified as placing patients at significantly increased risk for pneumonia. Patient-specific risk factors included age greater than 60 years, recent alcohol use, dependent functional status, long-term steroid use, and a 10% weight loss in the 6 months preceding the operation.²⁹

The diagnosis of postoperative pneumonia is based on the usual combination of index of suspicion, findings from the history and physical examination (e.g., fever, shortness of breath, hypoxia, productive cough, and rales on lung auscultation), imaging, and laboratory evaluation. Appropriate workup, directed by the clinical findings, typically starts with chest x-rays (preferably in both posteroanterior and lateral

views, if possible) and sputum cultures, sometimes accompanied by CT scanning of the chest and, possibly, bronchoscopy with bronchoalveolar lavage (which may be useful in directing antibiotic therapy when sputum cultures are non-diagnostic). Empirical broad-spectrum antibiotic therapy is typically initiated before the causative organism is identified; this practice has been shown to reduce mortality. Piperacillin-tazobactam, which is effective against *Pseudomonas aeruginosa*, is commonly used for this purpose; however, when Gram staining of the sputum identifies gram-positive cocci, vancomycin or linezolid may be used initially instead.³⁰ Once the causative organism is identified, specific antibiotic therapy directed at that organism is indicated, as in treatment of other infectious processes. Drainage of parapneumonic effusions may also be necessary, and this measure may be helpful in diagnosing or preventing the development of empyema.

SURGICAL SITE INFECTION

Surgical site infection (SSI) is one of the most common postoperative complications and may occur after virtually any type of procedure. Rates of infection vary widely (from less than 1% to approximately 20%) depending on the procedure performed, the classification of the operative wound (clean, clean-contaminated, contaminated, or dirty), and a host of patient-related and situation-specific factors. The majority of SSIs, regardless of site, are caused by skin-based flora, most commonly gram-positive cocci (e.g., staphylococci). Gram-negative infections are also commonly seen after GI procedures, and anaerobes may be present after pharyngo-esophageal procedures.³¹ With SSI, as with other postoperative infectious complications, prompt recognition of the signs and symptoms is the key to successful management. Hence, regular examination of the wound, particularly in the setting of postoperative fever, is critical. Erythema and induration (indicative of cellulitis) are obvious signs of SSI, as is active drainage of pus from the wound. A more subtle sign is pain that is greater than expected, especially when the pain seems to be increasing several days after operation.

In most cases, it is necessary to open and drain the wound (which is easily done at the bedside or in the clinic in most cases) and allow it to heal via secondary intention. Generally, wet-to-dry dressing changes with saline are employed; however, larger wounds may benefit from NPWT [see Care Orders, Wound Care, *above*]. Success with NPWT has been widely reported, and this technique has been used to treat difficult wounds such as exposed vascular grafts and sternotomy infections.^{32,33} The use of antibiotics depends on the presence and degree of cellulitis. The initial choice of an agent should be guided by the likelihood that particular organisms will be present, which is estimated on the basis of the site of the operation and the type of procedure being performed. Whenever possible, any purulent material in the SSI should be cultured; this step may permit more targeted antimicrobial therapy.

DEEP VEIN THROMBOSIS AND PULMONARY EMBOLISM

In the absence of appropriate prophylaxis, the incidence of DVT may be as high as 30% in abdominal and thoracic surgery patients and that of fatal pulmonary embolism (PE) may be as high as 0.9%. Thus, prophylaxis against thromboembolism is clearly of high importance in the postoperative

care of many patients. Major risk factors for DVT and PE in this setting include the operation itself, physical immobility, advanced age, the presence of a malignancy, obesity, and a history of smoking.³⁴

DVT should be suspected postoperatively whenever a patient complains of lower-extremity pain or one leg is noticeably more swollen than the other. The gold standard for diagnosis remains a venous duplex examination, which has a sensitivity of 97% for detecting DVT of the femoral and popliteal veins.³⁵ In most cases, treatment involves starting a heparin infusion (typically without a loading bolus in the postoperative setting), targeting a partial thromboplastin time (PTT) that is double to triple the normal PTT (i.e., approximately 60 to 80 seconds), and then switching to warfarin therapy when the patient is stable and able to tolerate oral medications.

PE should be suspected whenever a postoperative patient experiences a decrease in oxygen saturation or shortness of breath; this decrease may be accompanied by chest pain, tachycardia, and diaphoresis, all of which may also be seen in the setting of myocardial infarction (MI). When PE is suspected, it may be appropriate to start heparin therapy even before the diagnosis has been confirmed, depending on the degree of suspicion and the relative risk anticoagulation may pose to the patient. Currently, the principal means of diagnosing acute PE is spiral CT. This modality has relatively wide availability, can be performed fairly rapidly, and has a sensitivity of 53 to 100% and a specificity of 81 to 100%. In addition, it is readily usable in most critically ill patients, including those undergoing mechanical ventilation (although the amount of IV contrast material it requires may limit its use in patients with renal insufficiency). Greater diagnostic yield may be obtained by combining spiral CT with a lower-extremity venous duplex examination.³⁶ For most patients with postoperative PE, anticoagulation is administered in the form of heparin. Low-molecular-weight heparins (LMWHs) are also generally safe and effective; however, because their effect cannot be turned off in the same way as that of IV unfractionated heparin, they may be less useful in the period after operation.³⁷ In patients with massive PE, surgical embolectomy or suction-catheter embolectomy may be considered as conditions warrant. Thrombolytic therapy is generally contraindicated in the postoperative setting.

CARDIAC COMPLICATIONS

Cardiac dysrhythmias may occur after a wide variety of surgical procedures; as one might imagine, they are most common after cardiac operations. Predisposing factors and possible causes are numerous and various, including underlying cardiac disease, perioperative systemic stress, electrolyte and acid-base imbalances, hypoxemia, and hypercarbia. Thus, controlling such conditions to the extent possible both preoperatively and postoperatively is an important part of preventing and managing postoperative cardiac dysrhythmias. Treatment generally involves first achieving hemodynamic stability and then converting the rhythm back to sinus if possible.

Supraventricular tachycardias (SVTs) are the dysrhythmias most commonly seen in the postoperative period, occurring after approximately 4% of noncardiac major operations.

Atrial fibrillation and atrial flutter account for the majority of SVTs.³⁸ Ventricular rate control may be achieved pharmacologically by infusing diltiazem. Digoxin has long been used for this purpose but is less effective in acute settings than diltiazem is. Amiodarone, which is used to treat ventricular dysrhythmias, may also be used to restore sinus rhythm postoperatively in some cases, especially after cardiac procedures.³⁹ When pharmacologic rate control is not possible, particularly in hypotensive patients, cardioversion is indicated.

Approximately one third of patients who undergo noncardiac surgery in the United States have some degree of coronary artery disease and thus are at increased risk for perioperative MI. The incidence of coronary artery disease is even higher in certain subpopulations, such as patients who undergo major vascular procedures.^{40,41} In the perioperative setting, however, the pathophysiology of coronary ischemia is different from that in nonsurgical settings, where plaque rupture is the most common cause of MI. Approximately 50% of all MIs occurring in surgical patients are caused by increased myocardial oxygen demand in the face of inadequate supply resulting from factors such as fluid shifts, physiologic stress, hypotension, and the effects of anesthesia. The majority of cardiac ischemic events occur in the first 4 days of the postoperative period.⁴¹

Perioperative beta blockade for patients at risk for MI is now routine. Multiple trials and meta-analyses have demonstrated that this practice yields significant risk reductions in terms of both cardiac morbidity and mortality^{42,43} and that these risk reductions are achieved regardless of the type of surgery being performed. Although there has been some variation in the protocols used by these trials and the results reported, there is general agreement that beta blockade should be initiated preoperatively, delivered at the time of surgery, and continued postoperatively for up to 1 week.⁴²

Diagnosis of postoperative MI is complicated by the fact that as many as 95% of patients who experience this complication may not present with classic symptoms (e.g., chest pain). Identification of MI may be further hindered by the ECG changes brought on by the stress of the perioperative period (including dysrhythmias). Ultimately, the most useful signal of an ischemic cardiac event in the postoperative period is a rise in the levels of cardiac enzymes, particularly troponin I. Accordingly, cardiac enzyme activity should be assessed whenever there is a high index of suspicion for MI or a patient is considered to be at significant perioperative risk for MI.⁴⁰

Treatment of postoperative MI focuses on correcting any factors contributing to or exacerbating the situation that led to the event (e.g., hypovolemia or hypotension). Typically, although antiplatelet agents (e.g., aspirin) are sometimes given, thrombolytic therapy is avoided because of concerns about postoperative bleeding. Acute percutaneous coronary intervention is also associated with an increased risk of bleeding but has nonetheless been used successfully in the perioperative setting and is recommended by some physicians.⁴⁴ Beta blockade is often advocated as a means of treating postoperative MI, although it is probably more effective when used both preoperatively and perioperatively as a means of preventing MI.⁴⁰

Discharge

Planning for discharge from the hospital is clearly an essential part of perioperative care. In the best of circumstances, discharge planning starts before admission for elective surgery and is discussed with the patient and family as part of preoperative patient education. Starting the process early enables the provider to estimate the patient's probable needs at the end of acute hospitalization and thus to make preliminary arrangements as needed. For example, if it appears likely that the patient will have to stay in a skilled nursing or extended care facility or will require prolonged physical therapy and rehabilitation, these matters can be addressed to the mutual satisfaction of both patient and physician in advance of hospital discharge. In this way, delays in discharge and unnecessary days of acute hospitalization can be avoided, at least in some instances.

Criteria for discharge or transfer from acute hospital care vary widely depending on the procedure, the provider, and the patient; rarely are they codified. For example, in a 2005 survey of 16 surgeons performing open colorectal resections within one hospital, only two factors—absence of complications and reported postoperative bowel movement—were considered criteria for early discharge by most (but not all) of the surgeons.⁴⁵ There was wide disagreement on all other criteria, including postoperative mobility and the ability to tolerate a general diet. Given such variation in discharge criteria for even one category of procedure, it is clear that a discussion of specific criteria for each type of surgery is well beyond the scope of this chapter. It is worth pointing out, however, that the various discharge criteria now in use, despite their differences, have a common basis—namely, the idea that at discharge, the patient should ideally be able to manage basic self-care activities (e.g., feeding, wound care, and mobility) without advanced assistance and that the likelihood of readmission should be minimized to the extent possible. Identification, investigation, and control of factors such as nausea, pain, fever, deconditioning, and fatigue are important in determining whether a patient is at risk for a return to the hospital in the postoperative period.⁴⁶

Over the past two decades, critical pathways, which are organized plans that outline the sequence of patient care and discharge, have been increasingly used in managing postoperative care after a variety of procedures from all disciplines. They have been shown to reduce hospital stays and maintain safety in patients undergoing common procedures (e.g., colectomy), patients undergoing complex procedures (e.g., esophagectomy),⁴⁷ and patients with high comorbidity.⁴⁸ Individual pathways are typically specific to a hospital or health care system; thus, the discharge criteria are those agreed on by the providers involved in the care of eligible patients at that particular institution. Critical pathways can be helpful not only by standardizing care and improving the relative appropriateness of postoperative discharge but also, in many cases, by decreasing the overall length of postoperative hospitalization.⁴⁶ In a 2003 study of 27 postoperative critical pathways used at the Johns Hopkins Hospital, the authors found that seven (27%) of the pathways were associated with significant (5 to 45%) decreases in length of stay.⁴⁹

Regardless of whether critical pathways are implemented, if discharge planning is not addressed preoperatively,

addressing it as early as possible in the postoperative period is extremely valuable not only for ensuring an appropriate length of stay but also for maintaining the satisfaction and comfort of both patient and family. Specific issues should be addressed at this point as needed, including the home resources and support available to the patient, wound care, ostomy care, management of feeding tubes and drains, IV antibiotic therapy, and physical rehabilitation. Thus, as soon as it appears that a patient is on track either for discharge home or for transfer to a rehabilitation or skilled nursing facility, a discussion with the appropriate social work or discharge planning personnel should be scheduled. PT/OT evaluations early in the postoperative course can also be of great assistance in determining a patient's needs on discharge, and such evaluations are essential for any patient who may need a stay in an inpatient rehabilitation facility. Typically, it requires at least 1 day to set up services such as home health care and outpatient PT, and it may take this long or longer to obtain a bed at an appropriate rehabilitation or skilled nursing facility. Consequently, the earlier these plans are made, the better. For many surgical patients, formal discharge planning and PT/OT evaluations are not actually necessary. Brief discussions with the patient, the family, or the nursing staff caring for the patient will assist in determining which surgical patients are most likely to benefit from this approach.

Current Controversies in Postoperative Management

OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea (OSA) has rapidly become the most prevalent sleep disorder over the last 20+ years. At present, estimates suggest that it affects 9% of women and 24% of men in the United States. Additionally, estimates also suggest that as many as 82% of men and 92% of women affected do not carry the formal diagnosis of OSA.^{50,51} Despite the large percentage of the population affected, no well-validated specific guidelines are present in the current literature. That being said, there is a wealth of discussion of the issue from which several more general guidelines may be drawn.

Preoperative screening for OSA is the first and most critical step in management. As a majority of affected patients have not been formally diagnosed, this allows the operative team the opportunity to detect the greatest number of patients at risk and to adjust their operative plan of care accordingly.⁵² Most commonly, screening is done by anesthesiology in the preanesthesia setting using one of a number of available screening tools. In addition to this, it is important for the surgeon to also consider the potential presence of OSA as this may significantly affect the choice of surgical setting and postoperative setting planned.⁵³ Although, again, there are no set guidelines provided in the literature dictating criteria for outpatient versus inpatient surgical settings, for patients with known or suspected OSA requiring significant sedation or general anesthesia, using a setting with access to difficult airway carts, advanced respiratory care, and the option of a prolonged postanesthesia recovery unit (PACU) observation is recommended.⁵⁴

The two greatest issues in postoperative management are the level of monitoring provided and the use of sedatives and narcotic analgesics. The choice of surgical/postoperative

setting is best made after consideration of known or potential OSA, any associated comorbidities, and the type of surgery to be performed. Patients with severe OSA generally require inpatient monitoring postoperatively. Outside of known severe OSA, the time observed in the PACU may also provide further information on which to base ongoing care or discharge.⁵¹ Any patient who currently uses a home continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) device should use this in the immediate postoperative period.⁵⁵ In the inpatient setting, the use of continuous pulse oximetry and telemetry should be considered, and supplemental oxygen should be used with caution.^{53,55}

Anesthetics and sedatives depress the central nervous system, inhibit respiration, depress skeletal muscle tone, and relax the upper airway.⁵⁵ Opiate drugs can depress respiratory drive and rate, decrease tidal volume, and lead to decreased sensitivity to arousal. Thus, the use of sedatives postoperatively should be avoided or used with great caution. Narcotic agents need to be titrated to adequate pain relief but should be used only when nonnarcotic agents are ineffective. Additionally, the need for opiates may be significantly decreased with the use of nonnarcotic agents such as acetaminophen, centrally acting agents such as tramadol hydrochloride, NSAIDs, or topical anesthetics when appropriate.⁵³

The prevalence of OSA is only likely to increase given current trends in associated comorbidities such as obesity. Further prospective data are needed for more definitive future recommendations, particularly regarding postoperative monitoring and admission status.

POSTOPERATIVE ILEUS

Ileus, or the cessation of bowel function and transit in the absence of mechanical obstruction, is a common postoperative phenomenon particularly after abdominal surgery and occurs in virtually all patients undergoing bowel resection. Its causes are multifactorial, including an overall increase in sympathetic tone, the inflammatory response to bowel as a result of direct manipulation, and the well-known effects of narcotic analgesics on GI motility.⁵⁶ Although the typical duration of postoperative ileus averages around 3 days, in up to 32% of patients, return of bowel function may be particularly delayed.⁵⁷

Multiple strategies have been employed in attempts to decrease the length of postoperative ileus, such as early feeding, the use of chewing gum, and pharmacologic agents particularly directed at blocking the GI effects of narcotics. Feeding patients early (i.e., before evidence of return of bowel function) after abdominal surgery has been demonstrated to be generally safe and forms an element of many postoperative pathways. However, various studies comparing early feeding with awaiting return of bowel function have yielded mixed results, and no clear recommendation for early feeding can be made across all procedures.^{56,58} Chewing gum is thought to represent a sham-feeding condition that may have benefit in stimulating GI motility after abdominal surgery. It is safe; has few, if any, significant risks; and is well tolerated by patients. A recent meta-analysis of seven randomized, controlled trials comparing chewing gum with no gum after abdominal surgery concluded that gum leads to a clinically significant improvement in return of bowel function as represented by a sooner return of flatus.⁵⁹ However, not all individual trials have demonstrated a benefit.⁵⁶ Of the pharmacologic agents that have been investigated in the treatment of postoperative ileus, alvimopan, which is a selective antagonist of the peripheral opioid mu receptor, appears to confer the most significant benefit and was recently approved by the Food and Drug Administration for this indication. The recommended dose is 12 mg orally given twice daily for up to 7 days.^{57,60,61} Alvimopan was shown to reduce the return to GI tract function after bowel resection by 12 hours compared with placebo in a meta-analysis of five randomized, controlled trials involving a total of 1,877 patients.⁶² Further, it does not appear to have serious side effects.

Postoperative ileus remains a major factor in determining the length of hospital stay after abdominal surgery, particularly after bowel resection. Both chewing gum and alvimopan appear to provide some benefit in reducing the time to bowel recovery after surgery, with the former being the most simple and cost-effective to implement. None of these measures eliminate the effects of surgical intervention on GI motility entirely, however, and this will continue to be an area of active investigation in improving the care of the postoperative patient.⁵⁶⁻⁶²

6 POSTOPERATIVE PAIN

Spencer S. Liu, MD, and Henrik Kehlet, MD, PHD, FACS (Hon)

Clinical Approach to the Patient with Postoperative Pain

Postoperative pain consists of a constellation of unpleasant sensory, emotional, and mental experiences associated with autonomic, psychological, and behavioral responses precipitated by the surgical injury. Pain management has received increasing attention, and multiple government agencies and medical specialty organizations have now created guidelines for treatment of postoperative pain.¹ In 2001, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) introduced standards for pain management,² stating that patients have the right to appropriate evaluation and management and that pain must be assessed.

Postoperative pain relief has two practical aims. The first is provision of subjective comfort, which is desirable for humanitarian reasons. The second is inhibition of trauma-induced nociceptive impulses to blunt autonomic and somatic reflex responses to pain and to enhance subsequent restoration of function by allowing the patient to breathe, cough, and move more easily. Because these effects reduce pulmonary, cardiovascular, thromboembolic, and other complications, they may lead secondarily to improved postoperative outcome.

Inadequate Treatment of Pain

A common misconception is that pain, no matter how severe, can always be effectively relieved by opioid analgesics. It has repeatedly been demonstrated, however, that in a high proportion of postoperative patients, pain is inadequately treated.^{3,4} This discrepancy between what is possible and what is practiced can be attributed to a variety of causes [see Table 1], which to some extent can be ameliorated by increased teaching efforts. Recent evidence also indicates that overreliance on opioid therapy may be inherently limiting because of development of both acute tolerance and opioid-induced hyperalgesia.⁵ The ability of opioids in high doses or with chronic administration to potentially induce pain illustrates the importance of using multimodal analgesic regimens that target multiple analgesic pathways.

Guidelines for Postoperative Pain Treatment

In the past few years, efforts have been made to develop procedure-specific perioperative pain management guidelines. The impetus for these efforts has been the realization that the analgesic efficacy may be procedure dependent and that the choice of analgesia in a given case must also depend on the benefit-to-risk ratio, which varies among procedures. In addition, it is clear that some analgesic techniques will be considered only for certain specific operations (e.g., peripheral nerve blocks and intraperitoneal local anesthesia).⁶⁻⁸ At present, these procedure-specific guidelines are still largely in a developmental state and are available for laparoscopic cholecystectomy, open colon surgery, hysterectomy, inguinal hernia repair, thoracotomy, mastectomy, hemorrhoidectomy, and knee and hip replacement.^{9,10}

THORACIC PROCEDURES

Pain after thoracotomy is severe, and pain therapy should therefore include a combination regimen, preferably comprising epidural local anesthetics and opioids¹¹ combined with systemic nonsteroidal antiinflammatory drugs (NSAIDs) or cyclooxygenase-2 (COX-2) inhibitors (depending on risk factors) [see algorithm]. If the epidural regimen is not available, then comparable analgesia may be achieved with continuous thoracic paravertebral block, with

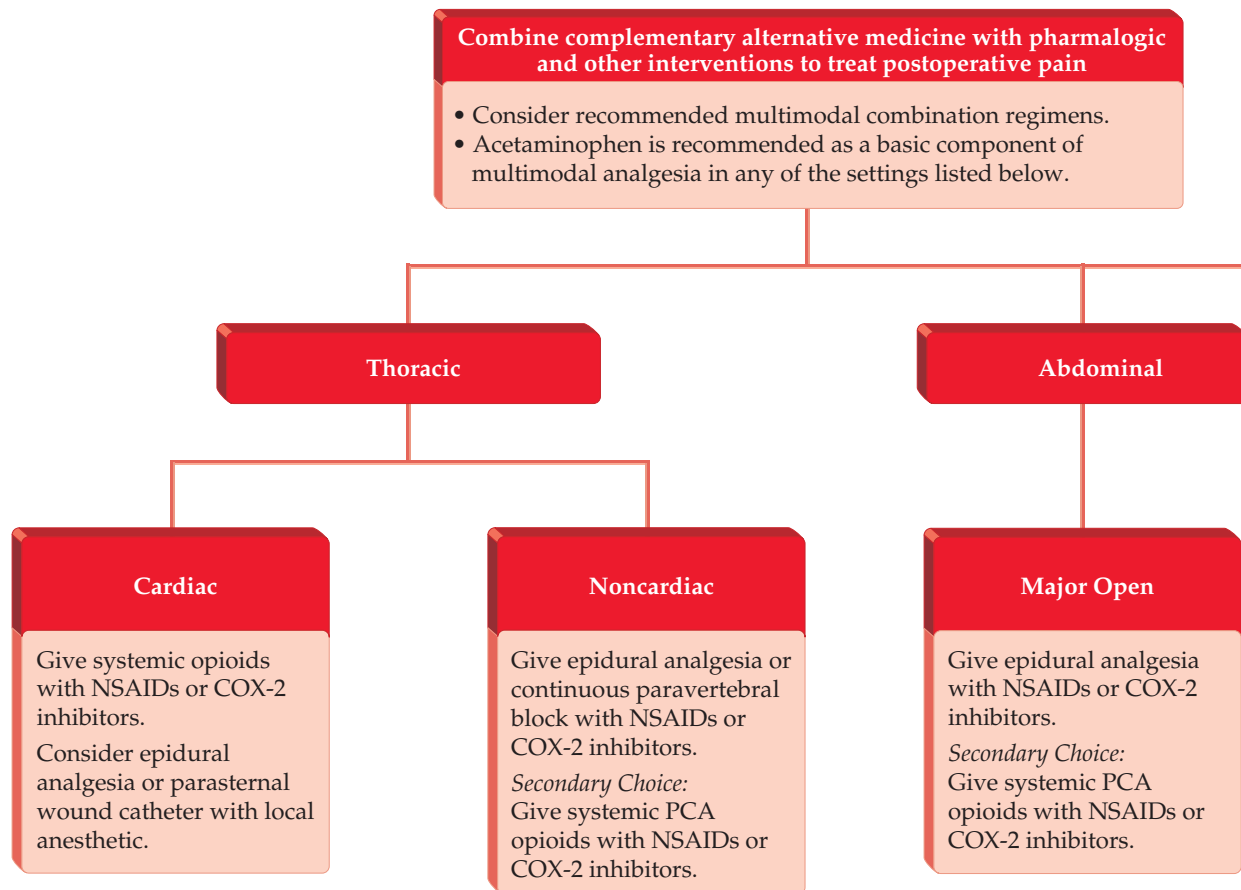

Table 1 Contributing Causes of Inadequate Pain Treatment

Insufficient knowledge of drug pharmacology among surgeons and nurses
Uniform (p.r.n.) prescriptions
Lack of concern for optimal pain relief
Failure to give prescribed analgesics
Fear of side effects
Fear of addiction

COX-2 = cyclooxygenase-2, NSAIDs = nonsteroidal antiinflammatory drugs; PCA = patient-controlled analgesia.

Clinical Approach to the Patient with Postoperative Pain

the potential for lesser incidence of urinary retention and postoperative nausea and vomiting.¹² Although comparable, the continuous paravertebral technique may be more technically difficult. If neither regional analgesic technique is available, then the inferior regimen of NSAIDs and systemic opioids may be used. Cryoanalgesia is not recommended as it is less effective.¹⁰ Acetaminophen is recommended as a basic analgesic for multimodal analgesia. Pain after cardiac operation with sternotomy is less severe, and systemic opioids plus NSAIDs are recommended. The combined regimen of epidural local anesthetics and opioids or parasternal wound catheters with continuous administration of local anesthetics¹³ is recommended when more effective pain relief is necessary, and it may reduce cardiopulmonary morbidity and perhaps length of stay.¹⁴

ABDOMINAL
PROCEDURES

Pain after major and upper open abdominal operations is severe, and a combined regimen of epidural local anesthetics and opioids is recommended because it has proved to be superior to systemic opioids and to have few and acceptable side effects.^{10,11,15} Furthermore, the epidural regimen will reduce postoperative pulmonary complications and ileus compared with treatment with systemic opioids.¹⁶ Systemic NSAIDs or COX-2 inhibitors are added when needed. Acetaminophen is recommended as a basic analgesic for multimodal analgesia.

After gynecologic lower abdominal or pelvic operations,¹⁰ systemic opioids plus NSAIDs or COX-2 inhibitors are recommended except in patients in whom more effective pain relief is desirable. In such patients, the combined regimen of epidural local anesthetics and opioids is preferable. Acetaminophen is recommended as a basic analgesic for multimodal analgesia.

Pain following prostatectomy is usually not severe and may be treated with systemic opioids combined with NSAIDs or COX-2 inhibitors and acetaminophen. However, blood loss and thromboembolic complications are reduced when epidural local anesthetics are administered. This method is therefore recommended intraoperatively and continued in selected high-risk patients for pain relief after open prostatectomy and transurethral resection. In low-risk patients, systemic opioids with NSAIDs or COX-2 inhibitors and acetaminophen alleviate postoperative pain.

PERIPHERAL
PROCEDURES

After vascular procedures, postoperative pain control is probably best achieved with epidural local anesthetic–opioid mixtures, combined with systemic NSAIDs or COX-2 inhibitors.¹¹ Acetaminophen is recommended as a basic analgesic for multimodal analgesia. This regimen will be effective, and the increase in peripheral blood flow that is documented to occur with epidural local anesthetics may lower the risk of graft thrombosis.

Pain relief after major joint procedures (e.g., hip and knee operations)¹⁰ may involve an epidural regimen in certain high-risk patients because such regimens have been shown to reduce thromboembolic complications and intraoperative blood loss and to improve physical rehabilitation when compared with systemic opioid regimens.^{17,18} However, the severe pain noted after knee replacement is probably best treated with peripheral nerve blocks.^{10,19} Most of the benefit of continuous femoral nerve analgesia may also be achieved with a single-injection femoral nerve block.²⁰ Total hip replacement is a less painful procedure, but when pain is severe, a continuous lumbar plexus or femoral nerve block can be used.^{10,21} Alternatively and with less technical expertise, a single intrathecal dose of local anesthetic and low-dose morphine will provide effective analgesia for the first 8 to 16 hours,¹⁰ after which NSAIDs or COX-2 inhibitors may be added. Acetaminophen is provided as a basic analgesic for multimodal analgesia.

Treatment Modalities

COMPLEMENTARY AND ALTERNATIVE MEDICINE
INTERVENTIONS

Cognitive, behavioral, alternative, or social interventions should be used in combination with pharmacologic therapies to prevent or control acute pain, with the goal of such interventions being to guide the patient toward partial or complete self-control of pain.^{22,23} A recent survey by the American Hospital Association indicated that 27% of member hospitals offered complementary and alternative medications (CAMs).²⁴ Use of nonpharmacologic adjunctive analgesics has been endorsed by advisory bodies such as the Anesthesia Patient Safety Foundation and Institute of Healthcare Improvement.^{25,26}

Psychological preparation in patients with postoperative pain has been demonstrated to shorten hospital stay and reduce postoperative narcotic use [see Table 2].²⁷ Guided imagery, relaxation, and music techniques have been demonstrated to reduce postoperative opioid use and affective pain.²² Acupuncture and acupressure has been successfully used as an adjunct for postoperative analgesia and reduces pain scores, anxiety levels, and postoperative nausea.²⁸ Alternative techniques

Table 2 Psychological Preparation of Surgical Patients	
Procedural information	Give a careful and relevant description of what will take place.
Sensory information	Describe the sensations that will be experienced either during or after the operation.
Pain treatment information	Outline the plan for administering sedative and analgesic medication and encourage patients to communicate concerns and discomforts.
Instructional information	Teach patients postoperative exercises, such as leg exercises, and show them how to turn in bed or move so that pain is minimal.
Reassurance	Reassure those who are mentally, emotionally, or physically unable to cooperate that they are not expected to take an active role in coping with pain and will still receive sufficient analgesic treatment.

Table 3 Opioid Receptor Types and Physiologic Actions

Receptor Type	Prototypical Ligand		Physiologic Actions
	Endogenous	Exogenous	
Mu ¹	β-Endorphin	Morphine	Supraspinal analgesia
Mu ²	β-Endorphin	Morphine	Respiratory depression
Delta	Enkephalin	—	Spinal analgesia
Kappa	Dynorphin	Ketocyclazocine	Spinal analgesia, sedation, visceral analgesia

should be combined with pharmacologic or other interventions, but care must be taken to ensure that the pharmacologic treatment does not compromise the mental function necessary for the success of the planned psychological intervention.

SYSTEMIC OPIOIDS

Mechanisms of Action

Opioids produce analgesia and other physiologic effects by binding to specific receptors in the peripheral and central nervous system (CNS) [see Table 3]. These receptors normally bind a number of endogenous substances called opioid peptides. These receptor-binding interactions mediate a wide array of physiologic effects.²⁹ Three types of opioid receptors and their subtypes have been discovered: mu, delta, and kappa receptors. The most commonly used opioids bind to mu receptors. The mu₁ receptor is responsible for the production of opioid-induced analgesia, whereas the mu₂ receptor appears to be related to the respiratory depression, cardiovascular effects, and inhibition of GI motility commonly seen with opioids.

The discovery of peripheral opioid receptors has led to investigation into potential clinical applications. Phase III studies with alvimopan (a peripheral opioid antagonist that does not cross the blood-brain barrier) have demonstrated reduced ileus and hospitalization after abdominal surgery.³⁰

Other studies have also investigated the analgesic effects of applying opioids to wound sites in an attempt to provide peripheral analgesia without central side effects. Unfortunately, neither incisional³¹ nor intra-articular³² opioid administration has demonstrated significant beneficial effect.³⁰ This finding may be attributable to the need for chronic inflammatory mediators to facilitate expression of peripheral opioid receptors.³³

The relation between receptor binding and the intensity of the resultant physiologic effect is known as the intrinsic activity of an opioid. Most of the commonly used opioid analgesics are agonists. An agonist produces a maximal biologic response by binding to its receptor. Other opioids, such as naloxone, are termed antagonists because they compete with agonists for opioid receptor-binding sites. Still other opioids are partial agonists because they produce a submaximal response after binding to the receptor. (An excellent example of a submaximal response produced by partial agonists is buprenorphine's action at the mu receptor.)

Drugs such as nalbuphine, butorphanol, and pentazocine are known as agonist-antagonists or mixed agonist-antagonists.²⁹ These opioids simultaneously act at different receptor sites: their action is agonistic at one receptor and antagonistic at another [see Table 4]. The agonist-antagonists have certain pharmacologic properties that are distinct from those of the more common mu agonists: (1) they exhibit a ceiling effect and cause only submaximal analgesia compared with mu agonists and (2)

administration of an agonist-antagonist with a complete agonist may cause a reduction in the effect of the complete agonist.²⁹

Agents

Morphine Morphine is the opioid with which the most clinical experience has been gained. Sufficient pharmacokinetic and pharmacodynamic data are available. Use of this agent is recommended; it may be given orally, intravenously (IV), or intramuscularly (IM).

Meperidine Detailed and sufficient pharmacokinetic and pharmacodynamic data on meperidine are available. It is less suitable than morphine as an analgesic because its active

metabolite, normeperidine, can accumulate, even in patients with normal renal clearance, and this accumulation can result in CNS excitation and seizures.²⁹ Other agents should be used before meperidine is considered. Like morphine, meperidine can be given orally, IV, or IM.

Side Effects

By depressing or stimulating the CNS, opioids cause a number of physiologic effects in addition to analgesia. The depressant effects of opioids include analgesia, sedation, and altered respiration and mood; the excitatory effects include nausea, vomiting, and miosis.

All mu agonists produce a dose-dependent decrease in the responsiveness of brainstem respiratory centers to increased carbon dioxide tension (P_{CO_2}). This change is clinically manifested as an increase in resting P_{CO_2} and a shift in the CO_2 response curve. Agonist-antagonist opioids have a limited effect on the brainstem and appear to elicit a ceiling effect on increases in P_{CO_2} .

Opioids also have effects on the gastrointestinal (GI) tract. Nausea and vomiting are caused by stimulation of the chemoreceptor trigger zone of the medulla. Opioids enhance sphincteric tone and reduce peristaltic contraction. Delayed gastric emptying is caused by decreased motility, increased antral tone, and increased tone in the first part of the duodenum. Delay in passage of intestinal contents because of decreased peristalsis and increased sphincteric tone leads to greater absorption of water, increased viscosity, and desiccation of bowel contents, which cause constipation and contribute to postoperative ileus. Opioids also increase biliary tract pressure. Finally, opioids may inhibit urinary bladder function, thereby increasing the risk of urinary retention.

Several long-acting, slow-release oral opioids are currently available, but their role (in particular, their safety) in the setting of moderate to severe postoperative pain remains to be established. In addition, modern principles of treatment increasingly emphasize the use of opioid-sparing analgesic approaches to enhance recovery (see below).

CLINICAL APPLICATION OF SYSTEMIC OPIOIDS

Traditional IM dosing of opioids is a suboptimal means of analgesia.³⁴ IM dosing does not result in consistent blood levels, because opioids are absorbed at a variable rate from the vascular bed of muscle. Moreover, administration of traditional IM regimens results in opioid concentrations that exceed the concentrations required to produce analgesia only

about 30% of the time during any 4-hour dosing interval. The optimal means to treat moderate to severe postoperative pain with systemic opioids is via IV patient-controlled analgesia (PCA). This delivery system compensates for the wide inter- and intraindividual variability in analgesic needs and blood levels after opioid administration. Self-delivery helps produce timely titration of analgesia and reduces administrative delay from conventional delivery (e.g., p.r.n.). Systematic reviews have noted that IV PCA delivery of opioids reduces pain scores and improves patient satisfaction over conventional delivery.³⁴ Typical regimens are provided in Table 5. Recent advances in iontophoretic technology have led to commercial release of a transdermal fentanyl iontophoretic PCA system. This system delivers 40 μ g fentanyl over 10 minutes after patient demand. Onset is rapid because of the active electrical current driving the fentanyl transdermally. The system deactivates after 24 hours or 80 administrations. Several clinical trials have reported equivalence between the fentanyl system and IV PCA opioid.³⁵ One pooled analysis suggested less analgesic gaps with the fentanyl system because of fewer technical failures and administrative delays than the IV PCA device³⁶; however, the role of this fentanyl system remains to be fully defined.

EPIDURAL AND SUBARACHNOID OPIOIDS

Opioids were first used in the epidural and subarachnoid spaces in 1979. Since that time, they have become the mainstay of postoperative management for severe pain. Epidural opioids may be administered in a single bolus or via continuous infusions. They are usually combined with local anesthetics in a continuous epidural infusion to enhance analgesia.³⁷

Mechanisms of Action

Opioids injected into the epidural or subarachnoid space cause segmental (i.e., selective, spinally mediated) analgesia by binding to opioid receptors in the dorsal horn of the spinal cord.³⁸ The lipid solubility of an opioid, described by its partition coefficient, predicts its behavior when introduced into the epidural or subarachnoid space. Opioids with low lipid solubility (i.e., hydrophilic opioids) have a slow onset of action and a long duration of action. Opioids with high lipid solubility (i.e., lipophilic opioids) have a quick onset of action but a short duration of action. This is attributable to more rapid diffusion across the dura into the spinal cord but also more rapid systemic uptake and clearance via uptake into

Table 5 Typical Intravenous Patient-Controlled Analgesia Regimens

Drug Concentration	Size of Bolus	Lockout Interval (min)
Agonists		
Morphine (1 mg/mL)		
Adult	0.5–2.5 mg	5–10
Pediatric	0.01–0.03 mg/kg (max. = 0.15 mg/kg/hr)	5–10
Fentanyl (0.01 mg/mL)		
Adult	10–20 μ g	4–10
Pediatric	0.5–1 μ g/kg (max. = 4 μ g/kg/hr)	5–10
Hydromorphone (0.2 mg/mL)		
Adult	0.05–0.25 mg	5–10
Pediatric	0.003–0.005 mg/kg (max. = 0.02 mg/kg/hr)	5–10

epidural and spinal cord blood vessels. In fact, current evidence suggests that a major site of action of spinal lipophilic opioids is not the spinal cord but the brain via systemic uptake.³⁹ Thus, lipophilic opioids as sole epidural analgesic agents are becoming less frequently recommended.

Subarachnoid opioids should be used when the required duration of analgesia after surgery is relatively short (< 24 hours) because of typical single-injection delivery. When protracted analgesia is required, epidural administration is preferred; repeated injections may be given through epidural catheters, or continuous infusions may be used. Smaller doses of subarachnoid opioids are generally required to produce analgesia. Ordinarily, no more than 0.1 to 0.25 mg of morphine should be used to provide 12 to 24 hours of analgesia. These doses, which are about 10 to 20% of the size of comparably effective epidural doses, provide reliable pain relief with few side effects.⁴⁰ Fentanyl has also been extensively used in the subarachnoid space in a dose range of 6.25 to 25 µg to provide 3 to 6 hours of analgesia. Recently, an extended duration formulation of epidural morphine has been commercially released.^{41–43}

This formulation consists of morphine encased in multivesicular lipid with predictable sustained release. Clinical studies have overall supported the efficacy and general safety of this formulation (10–15 mg doses) without demonstrating marked superiority over conventional central neuraxial opioid therapy. Thus, the role of this preparation remains to be determined.

Side Effects

The chief side effects associated with epidural and subarachnoid opioids are respiratory depression, nausea and vomiting, pruritus, and urinary retention.^{38,40,44} The poor lipid solubility of morphine is responsible for its protracted duration of action but also allows morphine to undergo cephalad migration in the cerebrospinal fluid (CSF). This migration can cause delayed respiratory depression, with a peak incidence 3 to 10 hours after an injection. The high lipid solubility of lipophilic opioids such as fentanyl allows them to be absorbed into lipids close to the site of administration. Consequently, the lipophilic opioids do not migrate rostrally in the CSF and cannot cause delayed respiratory depression. Of course, the high lipid solubility of lipophilic opioids allows them to be absorbed into blood vessels, which may cause early respiratory depression, as is commonly seen with systemic administration of opioids. Overall, the typical incidence of respiratory depression is similar to that seen with systemic opioids at approximately 0.2%.⁴⁴

Naloxone reverses the depressive respiratory effects of spinal opioids. In an apneic patient, 0.4 mg IV will usually restore ventilation. If a patient has a depressed respiratory rate but is still breathing, small aliquots of naloxone (0.2 to 0.4 mg) can be given until the respiratory rate returns to normal.

Nausea and vomiting are caused by transport of opioids to the vomiting center and the chemoreceptor trigger zone in the medulla via CSF flow or the systemic circulation. Nausea can usually be treated with antiemetics or, if severe, with naloxone (in 0.2 mg increments, repeated if necessary).

Pruritus is probably the most common side effect of the spinal opioids. Although not fully defined, the mechanism likely involves activation of “itch-specific” opioid receptors on spinal sensory neurons.⁴⁵ Although pruritus is commonly treated with antihistamines, there is minimal evidence for mechanism-specific effectiveness. An alternative and probably superior treatment is use of a mixed opioid agonist antagonist to directly block the opioid receptor–induced itching while maintaining opioid analgesias. Doses of 5 mg of nalbuphine IV or 2 to 4 mg of butorphanol intranasally or IV every 6 hours is commonly used.⁴⁵

The mechanism of spinal opioid–induced urinary retention involves inhibition of volume-induced bladder contractions and blockade of the vesical reflex. Naloxone administration is the treatment of choice, although bladder catheterization is sometimes required.

CLINICAL APPLICATION OF EPIDURAL AND SUBARACHNOID OPIOIDS

As stated earlier, subarachnoid opioids are limited in the duration of analgesia because of typical single-injection delivery. Epidural administration allows prolonged delivery of opioids, and typical regimens are listed in Table 6. However, side effects from opioids are common, and it is better to combine epidural opioids with local anesthetics to obtain multimodal and synergistic analgesia. This allows smaller doses of both agents to be used with better analgesia and fewer side effects. Typical regimens are listed in Table 7.

EPIDURAL LOCAL ANESTHETICS AND OTHER REGIONAL BLOCKS

Local anesthetic neural blockade is unique among available analgesic techniques in that it may offer sufficient afferent neural blockade, resulting in relief of pain; avoidance of sedation, respiratory depression, and nausea; and, finally, efferent sympathetic blockade, resulting in increased blood flow to the region of neural blockade.⁴⁶

Table 6 Typical Dosing of Neuraxial Opioids

Drug	Intrathecal or Subarachnoid Single Dose	Epidural Single Dose	Epidural Continuous Infusion
Fentanyl	5–25 µg	50–100 µg	25–100 µg/hr
Sufentanil	2–10 µg	10–50 µg	10–20 µg/hr
Morphine	0.1–0.3 mg	1–5 mg	0.1–1 mg/hr
Hydromorphone	—	0.5–1 mg	0.1–0.2 mg/hr
Meperidine	10–30 mg	20–60 mg	10–60 mg/hr

Lower doses may be effective when administered to the elderly or when injected in the cervical or thoracic region. Units vary across agents for single dose (mg versus µg) and continuous infusion (mg/hr versus µg/hr).

Table 7 Typical Patient-Controlled Epidural Analgesia Regimens

Analgesic Solution	Continuous Rate (mL/hr)	Demand Dose (mL)	Lockout Interval (min)
0.0625–0.125% bupivacaine + 2–5 µg/mL fentanyl	4–6	3–4	10–15
0.125–0.125% bupivacaine + 2–5 µg/mL sufentanil	3–5	2–3	12
0.1–0.2% ropivacaine + 2–4 µg/mL fentanyl	3–5	2–5	10–20

Mechanism of Action

Local anesthetic neural blockade is a nondepolarizing block that reduces the permeability of cell membranes to sodium ions.⁴⁷ Whether different local anesthetics have different effects on different nerve fibers is debatable.

Choice of Drug

For optimal management of postoperative pain, the anesthetic agent should provide excellent analgesia of rapid onset and long duration without inducing motor blockade. The various local anesthetic agents all meet one or more of these criteria; however, the ones that come closest to meeting all of the criteria are bupivacaine, ropivacaine, and levobupivacaine. This should not preclude the use of other agents, because their efficacy has also been demonstrated. Ropivacaine and levobupivacaine may have a better safety profile, but the improvement may be relevant only when high intraoperative doses are given.⁴⁷

Side Effects

The main side effects of epidural local anesthesia are hypotension caused by sympathetic blockade, vagal overactivity, and decreased cardiac function (during a high thoracic block). Under no circumstances should epidural local anesthetics be used before a preexisting hypovolemic condition is treated. Hypotension may be treated with ephedrine, 10 to 15 mg IV, and fluids, with the patient tilted in a head-down position. Atropine, 0.5 to 1.0 mg IV, may be effective during vagal overactivity.

Urinary retention occurs in 20 to 100% of patients, and urinary catheterization is typically used during epidural analgesia. Motor blockade may delay mobilization; however, its incidence can be reduced by using the weakest concentration of local anesthetic that is compatible with adequate sensory blockade.

The routine complications associated with the epidural catheter are minimal when proper nursing protocols are followed [see Table 8]. The decision to employ epidural local anesthetics in such patients should be made only after the risks^{44,48} are carefully compared with the documented advantages of such anesthetics.^{49,50}

Spinal hematoma attributable to the combination of epidural analgesia and anticoagulants is rare, but the risk may be increased by specific agents. Guidelines on the use of epidural analgesia and anticoagulation are currently listed on the American Society of Regional Anesthesia and Pain Medicine Web site.⁴⁸ Most anticoagulants can be safely managed with epidural analgesia; however, special care must be taken with thrombolytics, low-molecular-weight heparins, and newer antiplatelet, antithrombin, and anti-factor Xa agents.

CLINICAL APPLICATION OF CONTINUOUS EPIDURAL ANALGESIA

Typical regimens are listed in Table 7. As is similar with IV PCA, patient-controlled epidural analgesia (PCEA) has been demonstrated to provide superior analgesia, decreased analgesic consumption, and decreased side effects.⁵¹ The safety of PCEA regimens for hospital wards has been well documented.⁵² As all epidural analgesic agents are deliberately segmental (limited in anatomic spread) in nature, it is important for the vertebral site of epidural placement to match the site of surgery. For example, lumbar epidurals offer inferior analgesia to thoracic epidurals for thoracic surgery. Suggested epidural sites are also listed in Table 9.

OTHER REGIONAL ANALGESIA TECHNIQUES

Intraperitoneal administration of local anesthetics cannot be recommended for typical postoperative analgesia, because they are not efficacious,⁵³ except in laparoscopic cholecystectomy.^{8,10} Intra-incisional administration of bupivacaine or other long-acting local anesthetics, which has negligible side effects and demands little or no surveillance, is recommended for patients undergoing relatively minor procedures.

Continuous administration of local anesthetics into the wound via a catheter directly placed at the end of surgery is a simple and efficacious means to provide postoperative analgesia. A recent systematic review noted that wound catheters improved postoperative analgesia, reduced opioid

Table 8 Procedures for Maintenance of Epidural Anesthesia for Longer than 24 Hours

1. Administer appropriate drug in appropriate dosage at selected infusion rate as determined by physician
2. Nurse evaluates vital signs and intake and output as required for a postoperative patient
3. Nurse checks infusion pump hourly to ensure that it is functioning properly, that infusion rate is proper, and that alarm is on
4. Nurse also assesses
 - Bladder—for distention, if patient is not catheterized
 - Lower extremities—for status of motor function
 - Central nervous system—for signs of toxicity or respiratory depression
 - Skin integrity on back (breakdown may occur if motor function is not present)
 - Tubing and dressing (disconnection of tubing or dislodgment of catheter may occur)
5. Every 48 hr, the catheter dressing should be removed, the catheter entrance site cleaned, and topical antibiotic applied (much as in care of a central venous catheter)

Table 9 Recommended Location of Catheter Insertion for Surgical Procedures

Location of Incision	Examples of Surgical Procedures	Congruent Epidural Catheter Placement
Thoracic	Lung reduction, radical mastectomy, thoracotomy, thymectomy	T4–8
Upper abdominal	Cholecystectomy, esophagectomy, gastrectomy, hepatic section, Whipple procedure	T6–8
Middle abdominal	Cystoprostatectomy, nephrectomy	T7–10
Lower abdominal	Abdominal aortic aneurysm repair, colectomy, radical prostatectomy, total abdominal hysterectomy	T8–11
Lower extremity	Femoropopliteal bypass, total hip or total knee replacement	L1–4

L = lumbar; T = thoracic.

use, and decreased opioid-related side effects in a variety of procedures.¹³ However, there is still a need for more procedure-specific data before general recommendations can be made as a wide variety of surgical procedures, catheter locations, and analgesic regimens were included in the systematic review.

Continuous peripheral nerve blocks are growing in popularity, and the analgesic treatment may be continued after discharge.^{54,55} A systematic review has documented multiple benefits from the use of continuous perineural analgesia versus systemic opioids, such as reduced pain scores at rest and with activity, reduced opioid use, reduced opioid-related side effects, and increased patient satisfaction.⁵⁴ Use of outpatient perineural analgesia is also growing in popularity, and studies have observed that this form of analgesia reduces unplanned hospital admission after ambulatory procedures, improves patients quality of life at home, and may facilitate conversion of hospital procedures to short-stay procedures (e.g., total knee replacement).⁵⁶ A growing body of literature surveying the use of thousands of perineural catheters for postoperative analgesia documents a low incidence of complications and overall safety of this technique.⁵⁷ More recently, a high-volume infiltration technique with dilute concentrations of local anesthetics with or without adjuvants seems promising because of its apparent efficacy, simplicity, and safety.^{58,59}

NSAIDS, COX-2 INHIBITORS, AND ACETAMINOPHEN

NSAIDs and COX-2 inhibitors are modest analgesics that have both peripheral and central analgesic mechanisms and antiinflammatory effects [see Table 10]. Although these agents are typically less effective as sole analgesic agents than opioids,⁶⁰ they have an excellent efficacy to safety profile and are generally recommended after all kinds of operations for low-risk patients.^{61,62} Several reviews and systematic reviews report that NSAIDs and COX-2 inhibitors decrease systemic morphine use by approximately 13 to 18 mg over a 24-hour period.^{61,62} More importantly, these reviews indicate that NSAIDs decrease pain scores by approximately 1 cm on a 10 cm visual analogue scale pain score and reduce opioid-related side effects of sedation and nausea by approximately 30%. Conventional NSAIDs inhibit both COX-1 and COX-2. Selective COX-2 inhibitors, which do not inhibit COX-1, have the potential to achieve analgesic efficacy comparable to that of conventional NSAIDs but with fewer minor side effects.^{63–65}

Only a few of the NSAIDs may be given parenterally. The data now available on the use of NSAIDs for postoperative pain are insufficient to allow definitive recommendation of

any agent or agents over the others, and selection therefore may depend on the convenience of delivery, duration, and cost.⁶⁶ All of the NSAIDs have potentially serious side effects: GI and surgical site hemorrhage, renal failure, impaired bone healing, and asthma. The endoscopically verified superficial ulcer formation seen within 7 to 10 days after the initiation of NSAID therapy is not seen with selective COX-2 inhibitor treatment in volunteers. The clinical relevance of these findings for perioperative treatment remains to be established, however, given that acute severe GI side effects (bleeding, perforation) are extremely rare in elective cases.

Because prostaglandins are important for regulation of water and mineral homeostasis by the kidneys in the dehydrated patient, perioperative treatment with NSAIDs, which inhibit prostaglandin synthesis, may lead to postoperative renal failure. So far, specific COX-2 inhibitors have not been demonstrated to be less nephrotoxic than conventional NSAIDs.^{62,67} Although little systematic evaluation has been done, extensive clinical experience with NSAIDs suggests that the renal risk is not substantial.⁶⁸ Nonetheless, conventional NSAIDs and COX-2 inhibitors should be used with caution in patients who have preexisting renal dysfunction.⁶²

Although conventional NSAIDs prolong bleeding time and inhibit platelet aggregation, there generally does not seem to

Table 10 Typical Dosing for Common NSAIDs, COX-2 Inhibitors, and Acetaminophen

Drug	Typical Dose for Postoperative Analgesia	Maximum Recommended Dose (mg/day)
Acetaminophen	650–1,000 mg q 6 hr	4,000
Celecoxib	100–200 mg q 12 hr	400
Diclofenac	50 mg q 8 hr	150
Ibuprofen	400 mg q 6 hr	3,200
Indomethacin	25–50 mg q 8 hr	200
Ketorolac	10 mg q 4–6 hr	40
Ketorolac (intravenous)	15–30 mg q 6 hr	120
Meloxicam	7.5–15 mg q day	15
Naproxen	250 mg q 6–8 hr	1,375
Paracetamol (intravenous)	1,000 mg q 6 hr	4,000

COX-2 = cyclooxygenase; NSAIDs = nonsteroidal antiinflammatory drugs.

be a clinically significant risk of increased bleeding. However, in some procedures for which strict hemostasis is critical (e.g., tonsillectomy, cosmetic surgery, and eye surgery), these drugs have been shown to increase the risk of bleeding complications and should therefore be replaced with COX-2 inhibitors, which do not inhibit platelet aggregation.⁶⁹ The observation that prostaglandins are involved in bone and wound healing has given rise to concern about potential side effects in surgical patients. Although there is experimental evidence that both conventional NSAIDs and COX-2 inhibitors can impair bone healing,⁷⁰ the clinical data available at present are insufficient to document increased wound or bone healing failure with these drugs.⁷¹ This is a particularly important issue for future study in that many orthopedic surgeons remain reluctant to use NSAIDs.

Currently, there is widespread concern about the increased risk of cardiovascular complications associated with long-term treatment with selective COX-2 inhibitors. Generally, such side effects have appeared only after 1 to 2 years of treatment and led to the withdrawal of rofecoxib in 2004 and valdecoxib in 2005 from the US market.⁷² In the past few years, however, two studies of patients undergoing coronary artery bypass grafting (CABG) found that the risk of cardiovascular complications was increased significantly (two- to threefold) in this setting and led to the label change for COX-2 inhibitors and NSAIDs indicating that these agents are contraindicated in CABG patients.⁷² The larger question is whether these drugs should also be contraindicated for perioperative use, or at least used with caution, in high-risk cardiovascular patients who are undergoing procedures other than CABG. At present, the data are insufficient to allow final conclusions; nonetheless, reviews suggest that the benefits of short-term use of these agents in patients without cardiovascular risk factors probably outweigh the potential (low) risk of complications. Until further studies are performed, use in patients with cardiovascular risk factors should be cautious.⁷²

Acetaminophen also possesses analgesic capability, both peripherally and centrally. Its analgesic effect is somewhat (about 20 to 30%) weaker than those of conventional NSAIDs and COX-2 inhibitors. For example, use of acetaminophen typically reduces morphine consumption by approximately 9 mg over a 24-hour period,⁶¹ which may be insufficient to significantly reduce opioid-related side effects or dramatically improve analgesia. However, acetaminophen lacks the side effects typical of NSAIDs.⁶² Combining acetaminophen with NSAIDs may improve analgesia, especially in smaller and moderate-sized operations^{73,74}; accordingly, this agent is recommended as a basic component of multimodal analgesia in all operations.

OTHER ANALGESICS

Glucocorticoids are powerful antiinflammatory agents and have proven analgesic value in less extensive procedures,^{75,76} especially dental, laparoscopic, and arthroscopic operations. In addition, they have profound antiemetic effects.⁷⁷ Concerns about possible side effects in the setting of perioperative administration have not been borne out by the results of randomized studies.^{75,76}

Tramadol is a weak analgesic that has several relatively minor side effects (e.g., dizziness, nausea, and vomiting) and possesses weak opioid agonist activity and inhibits reuptake

of serotonin and norepinephrine.⁷⁸ It can be used as an intravenous analgesic but is less potent than opioids (morphine, meperidine)⁷⁹ and is a poor sole agent for control of postoperative pain.⁸⁰

Several systematic reviews have suggested that some analgesic and perioperative opioid-sparing effects can be achieved by adding an *N*-methyl-d-aspartate (NMDA) receptor antagonist (e.g., ketamine), gabapentin, or pregabalin [see Combination Regimens, below].^{34,81}

TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

Transcutaneous electrical nerve stimulation (TENS) is the application of a mild electrical current through the skin surface to a specific area, such as a surgical wound, to achieve pain relief; the exact mechanism whereby it achieves this effect is yet to be explained but may involve spinal gating and activation of opioid receptors. Although several randomized controlled trials have reported efficacy after inguinal herniotomy,⁸² thoracotomy,⁸³ and other procedures,⁸⁴ the specific values and the proper uses of the various stimulation frequencies, waveforms, and current intensities have not been determined. In addition, blinding of subjects is difficult with TENS studies, and this effect of bias is difficult to assess. Overall, the effect of TENS on acute pain is too imprecise to warrant a recommendation for routine use.⁸⁵

COMBINATION REGIMENS

Because no single pain treatment modality is optimal, combination regimens (e.g., balanced analgesia or multimodal treatment) offer major advantages over single-modality regimens, whether by maintaining or improving analgesia, by reducing side effects, or by doing both.⁸⁶ Combinations of epidural local anesthetics and morphine,^{15,44} of NSAIDs and opioids,^{66,87,88} of NSAIDs and acetaminophen,^{73,74} of acetaminophen and opioids,⁸⁹ of acetaminophen and tramadol,⁹⁰ and of a selective COX-2 inhibitor and gabapentin⁹¹ or pregabalin⁸¹ have been reported to have additive effects. At present, information on other combinations (involving ketamine, clonidine, glucocorticoids, and other agents) is too sparse to allow firm recommendations; however, multimodal analgesia is undoubtedly promising, and multidrug combinations should certainly be explored further.

The potential of combination regimens is especially intriguing with respect to the concept of perioperative opioid-sparing analgesia. The use of one or several nonopioid analgesics in such regimens may enhance recovery in that the concomitant reduction in the opioid dosage will lead to decreased nausea, vomiting, and sedation.^{92–95} Both the adverse events associated with postoperative opioid analgesia and the relatively high costs of such analgesia argue for an opioid-sparing approach.^{96,97} The ability to reduce opioid-related and non-opioid-related side effects by use of multimodal analgesia may become especially attractive for several reasons. First, there is growing evidence that the use of opioids as sole analgesics can lead to opioid-induced hyperalgesia, whereby overstimulation of opioid receptors creates a nociceptive state (i.e., opioids increase sensitivity to painful stimuli).⁹⁸ Also, in light of the JCAHO pain initiative and overall increased focus on reducing pain,¹ a concern exists that these initiatives may precipitate increased use of opioids and thereby an increased risk of side effects.^{99,100}

Discussion

Physiologic Mechanisms of Acute Pain

The noxious stimuli from iatrogenic surgical injury or accidental trauma set a cascade of events in motion cumulating in the perception of “pain.” Many interrelated components contribute to the processing of nociceptive stimuli. Clinicians should recognize that the neurobiology of nociception is extremely complex, with multiple levels of redundancy, such that there is no “hardwired” or “final common” pathway for the process of nociception of acute pain. The basic mechanisms are (1) afferent transmission of nociceptive stimuli through the peripheral nervous system after tissue damage, (2) modulation of these injury signals by control systems in the dorsal horn, and (3) modulation of the ascending transmission of pain stimuli by a descending control system originating in the brain [see Figure 1].^{101–103}

PERIPHERAL PAIN RECEPTORS AND NEURAL TRANSMISSION TO THE SPINAL CORD

Peripheral pain receptors (nociceptors) can be identified by function but cannot be distinguished anatomically. The responsiveness of peripheral pain receptors may be enhanced by endogenous analgesic substances (e.g., prostaglandins, serotonin, bradykinin, nerve growth factor, and histamine), as well as by increased efferent sympathetic activity.¹⁰¹ Antidromic release of substance P may amplify the inflammatory response and thereby increase pain transmission. The peripheral mechanisms of visceral pain are different from somatic or neuropathic nociception and likely involve transient receptor potential vanilloid 1 receptors, acid-sensing ion channels, and tachykinins.¹⁰⁴ Peripheral opioid receptors have been demonstrated to appear in inflammation on the peripheral nerve terminals but probably have little clinical relevance.^{31–33} Somatic nociceptive input is transmitted to the CNS through A-delta and C fibers, which are small in diameter and either unmyelinated or thinly myelinated. Visceral pain is transmitted through afferent sympathetic pathways; the evidence that afferent parasympathetic pathways play a role in visceral nociception is inconclusive.^{104,105}

DORSAL HORN CONTROL SYSTEMS AND MODULATION OF INCOMING SIGNALS

All incoming nociceptive traffic synapses in the gray matter of the dorsal horn (Rexed laminae I to IV). Several substances may be involved in primary afferent transmission of nociceptive stimuli in the dorsal horn: substance P, enkephalins, somatostatin, neurotensin, γ -aminobutyric acid (GABA), glutamic acid, angiotensin II, vasoactive intestinal polypeptide (VIP), and cholecystokinin octapeptide (CCK-8).^{102,106} From the dorsal horn, nociceptive information is transmitted through the spinothalamic tracts to the hypothalamus, through spinoreticular systems to the brainstem and reticular formation, and finally to the cerebral cortex.

DESCENDING PAIN CONTROL SYSTEM

A descending control system for sensory input originates in the brainstem and reticular formation and in certain higher brain areas. The main neurotransmitters in this system are norepinephrine, serotonin, acetylcholine, and enkephalins. Stimulation

or augmentation of this descending system enhances analgesia. Epidural-intrathecal administration of alpha-adrenergic agonists (e.g., clonidine) or of anticholinesterases (e.g., neostigmine) works in this manner to provide pain relief.⁹⁴

SPINAL REFLEXES

Nociception may be enhanced by spinal reflexes that affect the environment of the nociceptive nerve endings. Thus, tissue damage may provoke an afferent reflex that causes muscle spasm in the vicinity of the injury, thereby increasing nociception. Similarly, sympathetic reflexes may cause decreased microcirculation in injury tissue, thereby generating smooth muscle spasm, which amplifies the sensation.

POSTINJURY CHANGES IN PERIPHERAL AND CENTRAL NERVOUS SYSTEMS

After an injury, the afferent nociceptive pathways undergo physiologic, anatomic, and chemical changes.^{102,103} These changes include increased sensitivity on the part of peripheral nociceptors, as well as the growth of sprouts from damaged nerve fibers that become sensitive to mechanical and alpha-adrenergic stimuli and eventually begin to fire spontaneously. Moreover, excitability may be increased in the spinal cord, which leads to expansion of receptive fields in dorsal horn cells. Such changes may lower pain thresholds, may increase afferent barrage in the late postinjury state, and, if normal regression does not occur during convalescence, may contribute to a chronic pain state.¹⁰²

Neural stimuli have generally been considered to be the main factor responsible for initiation of spinal neuroplasticity; however, it now appears that such neuroplasticity may also be mediated by cytokines released as a consequence of COX-2 induction.¹⁰³ Improved understanding of the mechanisms of pain may serve as a rational basis for future drug development and may help direct therapy away from symptom control and toward mechanism-specific treatment.¹⁰⁷

In experimental studies, acute pain behavior or hyperexcitability of dorsal horn neurons may be eliminated or reduced if the afferent barrage is prevented from reaching the CNS. Preinjury neural blockade with local anesthetics or opioids can suppress excitability of the CNS; this is called preemptive analgesia. Although this has been a consistent finding in laboratory studies, clinical studies have been less dramatic. A critical analysis of controlled clinical studies that compared the efficacy of analgesic regimens administered preoperatively with the efficacy of the same regimens administered postoperatively concluded that preemptive analgesia does not always provide a clinically significant increase in pain relief.^{108,109} Nonetheless, it is important that pain treatment be initiated early to ensure that patients do not wake up with high-intensity pain.

Effects of Pain Relief

SELECTED PHYSIOLOGIC RESPONSES TO OPERATION

Cardiovascular

It has traditionally been thought that an imbalance of myocardial oxygen supply and demand, such as an increase in

Figure 1 Shown are the major neural pathways involved in nociception. Nociceptive input is transmitted from the periphery to the dorsal horn via A-delta and C fibers (for somatic pain) or via afferent sympathetic pathways (for visceral pain). It is then modulated by control systems in the dorsal horn and sent via the spinothalamic tracts and spinoreticular systems to the hypothalamus, to the brainstem and reticular formation, and eventually to the cerebral cortex. Ascending transmission of nociceptive input is also modulated by descending inhibitory pathways originating in the brain and terminating in the dorsal horn. Nociception may be enhanced by reflex responses that affect the environment of the nociceptors, such as smooth muscle spasm. CCK = cholecystokinin-octapeptide; GABA = γ -aminobutyric acid; VIP = vasoactive intestinal peptide.

demand (e.g., increase in heart rate or blood pressure) or a decrease in supply (e.g., decreased coronary blood flow to the vulnerable subendocardial areas), may contribute to perioperative cardiac events, particularly in patients with decreased cardiac reserve.¹¹⁰ Although many factors may contribute to an imbalance of myocardial oxygen supply and demand,

uncontrolled postoperative pain may be especially detrimental and contribute to cardiac morbidity through activation of the sympathetic nervous system, other surgical stress responses, and the coagulation cascade. Increased sympathetic nervous system activity can increase myocardial oxygen demand by increasing heart rate, blood pressure, and

contractility or even decrease myocardial oxygen supply, which, in turn, may lead to angina, dysrhythmias, and areas of myocardial infarction.¹¹⁰ In addition, sympathetic activation may enhance perioperative hypercoagulability, which may contribute to perioperative coronary thrombosis or vasospasm, thus reducing myocardial oxygen supply.¹¹¹

Pulmonary

The pathophysiology of pulmonary dysfunction after surgery is multifactorial. Relevant factors include disruption of normal respiratory muscle activity, which may result from either surgery or anesthesia, reflex inhibition of phrenic nerve activity with subsequent decrease in diaphragmatic function, and uncontrolled postoperative pain, which may contribute to voluntary inhibition of respiratory activity, or splinting.¹¹² Although the pathophysiology of breathing and respiratory muscle function following surgery is complex, it is clear that anesthetic or analgesic agents administered in the perioperative period affect the central regulation of breathing and activities of respiratory muscles. This incoordination of respiratory muscle function (which may last well into the postoperative period) will impair lung mechanics, increasing the risk of hypoventilation, atelectasis, and pneumonia. Visceral stimulation may decrease phrenic motoneuron output, which results in a decrease in diaphragmatic descent and lung volumes.¹¹²

Gastrointestinal

Although decreased GI motility is expected after abdominal surgery, return of GI function usually occurs within several days postoperatively. Some patients will develop paralytic ileus, a protracted and more severe state of GI immotility. Although the pathophysiology of postoperative ileus and decreased GI motility is multifactorial, the primary mechanisms include neurogenic (spinal, supraspinal adrenergic pathways), inflammatory (i.e., local inflammatory responses initiate neurogenic inhibitory pathways), and iatrogenic pharmacologic (e.g., opioids) mechanisms.¹¹³ In the acute postoperative phase, neurogenic (spinal and supraspinal) mechanisms are primary mediators of decreased GI motility.¹¹³ Activation of splanchnic afferents and increased sympathetic outflow, along with the possible use of opioids, are the predominant mechanisms for decreased GI motility immediately following surgery. However, over the subsequent postoperative days, a prolonged phase of postoperative ileus occurs. The presumed etiology of the latter is distinct and involves an enteric molecular inflammatory response that impairs local neuromuscular function and activates neurogenic inhibitory pathways.¹¹³ Our understanding of the mechanisms of postoperative ileus is not complete, and it is likely that these three mechanisms are not discrete phenomena but interrelated.

Coagulation

It is recognized that hypercoagulability occurs in association with surgical procedures. Although the pathophysiology of coagulation-related events (e.g., formation of deep vein thrombosis has essentially been unchanged since Virchow's initial description of the triad of stasis, blood vessel injury, and hypercoagulability, our current understanding of the coagulation system is that it is a complex system with many

other functions, including tissue repair, autoimmune regulation, arteriosclerosis, and tumor growth and metastasis.¹¹⁴ Nevertheless, the primary components of the coagulation systems comprise cellular (e.g., platelets, endothelial cells, monocytes, and erythrocytes) and molecular (e.g., coagulation factors and inhibitors, fibrinolysis factors and inhibitors, adhesive and intercellular proteins, acute-phase proteins, immunoglobulins, phospholipids, prostaglandins, and cytokines) components.¹¹⁴ The normal process of coagulation involves several steps, including initiation (damaged vascular endothelium expresses tissue factor, which ultimately leads to generation of thrombin), amplification (augmentation of the effects of thrombin), propagation (formation of clot), and stabilization (formation of a stable fibrin meshwork that protects clot from fibrinolytic attack).¹¹⁴ However, following surgery, the normal process of coagulation may become unbalanced, which may result in a tendency toward thrombosis. Immediately after surgical incision, there are increases in the levels of tissue factor, tissue plasminogen activator, plasminogen activator inhibitor-1, and von Willibrand factor, which contribute to a hypercoagulable and hypofibrinolytic state postoperatively.¹¹⁴ Many of these detrimental responses may be reduced by excellent postoperative analgesia and in particular by the sympathetic and afferent block provided by thoracic epidural analgesia with local anesthetics.

POSTOPERATIVE MORBIDITY

Despite excellent theoretical reasons why high-quality analgesia should improve postoperative physiology and outcomes, the effects of nociceptive blockade and pain relief on postoperative morbidity remain controversial.¹⁶ There are several likely reasons why these effects are difficult to assess. Primarily, surgical techniques and perioperative care are constantly evolving and improving, with subsequent reduction in baseline morbidity and mortality. Thus, the positive effects of analgesia on outcomes may be apparent only on selected high-risk patients or procedures. Several systematic reviews have examined this question and have reached the following conclusions. For open major vascular and thoracic procedures, there is good evidence from systematic reviews and large randomized controlled trials that thoracic epidural analgesia may reduce cardiovascular and pulmonary morbidity when compared with systemic opioids.¹⁶ There is good evidence from meta-analyses that intraoperative spinal or epidural local anesthetics in lower-body procedures reduce estimated blood loss by about 30%.^{17,115} Finally, the duration of postoperative ileus is reduced by approximately 24 to 36 hours with the use of epidural analgesia with local anesthetic-containing solutions after major open abdominal procedures.¹⁶ This effect may be of major significance in that reduction of ileus allows earlier oral nutrition,⁵⁰ which has been demonstrated to improve outcome.

Another key feature in the difficulties assessing the impact of postoperative analgesia is that most studies to date have focused on the effects of a single factor (i.e., epidural analgesia) on overall postoperative morbidity. In current medical practice, this is probably too simplistic an approach as overall postoperative outcome is known to be determined by multiple factors.¹¹⁶⁻¹¹⁸ Besides postoperative pain relief, reinforced

psychological preparation of the patient, reduction of stress by performing neural blockade or opting for minimal invasive procedures, and enforcement of early oral postoperative feeding and mobilization may all play a significant role in determining outcome.¹¹⁸ Prevention of intraoperative hypothermia, avoidance of fluid overloading, and avoidance of hypoxemia may be important as well.^{118,119} Therefore, although adequate pain relief is obviously a prerequisite for good outcome, the best results are likely to be achieved by combining analgesia with all of the aforementioned factors in a multimodal rehabilitation effort.

DEVELOPMENT AND PREVENTION OF CHRONIC POSTOPERATIVE PAIN

Although not all nociceptive input results in a pathologic process, a substantial percentage of patients who undergo certain surgical procedures will exhibit prolonged central sensitization and chronic pain [see Table 11]. Pathologic nociceptive input may cause central sensitization, which is marked by hyperexcitable spinal neurons that exhibit a decreased threshold for activation, increased and prolonged response to noxious input, expansion of receptive fields, possible spontaneous activity, and activation by normally non-noxious stimuli.¹²⁰

Induction and maintenance of central sensitization emphasize different receptor-neurotransmitter combinations, including NMDA receptors, prostaglandins, and neuropeptides (substance P, calcitonin gene–related peptide, neurokinin A).¹²¹ Ultimately, transcriptional changes (including induction of genes), structural changes in synaptic connections (e.g., contact between low-threshold afferent and nociceptive neurons), and loss of inhibitory interneurons may result in a persistent state of central sensitization.¹²²

Multiple studies and reviews have noted that more severe acute postoperative pain is a risk factor for development of chronic postoperative pain.^{61,123} Although optimal strategies for prevention of chronic pain have not been identified, promising modalities include preemptive regional analgesia such as thoracic epidural local anesthetics, NMDA antago-

nists, and anticonvulsant analgesia adjuncts such as gabapentin.^{61,124,125} Future studies will need to define optimal strategies for high-risk procedures and patients.

BARRIERS TO EFFECTIVE POSTOPERATIVE ANALGESIA

In general, multiple advisory and supervisory organizations (e.g., JCAHO, World Health Organization) recognize the importance of adequate pain control.¹ Partially in response to these initiatives, there has been a marked increase in the creation and requirement of acute pain treatment services within hospitals across the world.¹²⁶ Work continues on attempting to create efficient and simple delivery techniques and technologies for postoperative analgesia. In addition to economic constraints, significant concerns regarding potential for opioid tolerance and addiction remain as a barrier.¹ Continued exposure of an opioid receptor to high concentrations of opioid will cause tolerance. Tolerance is the progressive decline in an opioid's potency with continuous use, so higher and higher concentrations of the drug are required to cause the same analgesic effect. Physical dependence refers to the production of an abstinence syndrome when an opioid is withdrawn. It is defined by the World Health Organization as follows:

A state, psychic or sometimes also physical, resulting from interactions between a living organism and a drug, characterized by behavioural and other responses that always include a compulsion to take the drug on a continuous or periodic basis in order to experience its psychic effects, and sometimes to avoid discomfort from its absence.¹²⁷

This definition is very close to the popular concept of addiction. It is important, however, to distinguish addiction (implying compulsive behavior and psychological dependence) from tolerance (a pharmacologic property) and from physical dependence (a characteristic physiologic effect of a group of drugs). Physical dependence does not imply addiction. Moreover, tolerance can occur without physical dependence; the converse does not appear to be true. The possibility that the medical administration of opioids could result in a patient becoming addicted has generated much debate about the use

Table 11 Approximate Incidences and Risk Factors for Development of Postoperative Chronic Pain

Surgical Procedure	Incidence of Chronic Pain (%)	Risk Factors
Thoracotomy	30–70	Increased acute pain
		Open vs thoracoscopic
		Not using thoracic epidural analgesia with local anesthetics
		Intercostal nerve injury
Mastectomy	11–60	Increased acute pain
		Increased acute opioid consumption
		Immediate adjuvant radiation therapy
		Axillary dissection vs sentinel node biopsy
Inguinal hernia repair	0–37	Increased acute pain
		Preoperative pain
		Female gender
		Surgery for recurrent hernia
		Open vs laparoscopic

of opioids. In a prospective study of 12,000 hospitalized patients receiving at least one strong opioid for a protracted period, there were only four reasonably well-documented cases of subsequent addiction, and in none of these was there a history of previous substance abuse.¹²⁸ Thus, the iatrogenic production of opioid addiction is very rare. It is hoped that continued physician and patient education will reduce this barrier to high-quality postoperative analgesia.

Conclusion

The choice of therapeutic intervention for acute postoperative pain is determined largely by the nature of the patient's problem, the resources available, the efficacy of the various

treatment techniques, the risks attendant on the procedures under consideration, and the cost to the patient. It is to be hoped that our growing understanding of basic pain mechanisms and appropriate therapy, combined with the promising data supporting the idea that adequate inhibition of surgically induced nociceptive stimuli may reduce postoperative morbidity, will stimulate more surgeons to turn their attention to this area. Effective control of postoperative pain, combined with a high degree of surgical expertise and the judicious use of other perioperative therapeutic interventions within the context of multimodal postoperative rehabilitation, is certain to improve acute and long-term patient outcomes.

7 ACUTE WOUND CARE

Stephen R. Sullivan, M.D., Loren H. Engrav, M.D., F.A.C.S., and Matthew B. Klein, M.D.

Approach to Acute Wound Management

Acute wounds are the result of local trauma and may be associated with severe life-threatening injuries. The approach to a patient with an acute wound begins with assessment of the ABCs (Airway, Breathing, and Circulation). Management of any life-threatening injuries present is addressed first; only after more urgent problems have been ruled out or corrected is management of the wound itself addressed. A complete history is obtained and a thorough physical examination performed, with special attention paid to both local and systemic wound environment factors that may affect healing. Information about the cause of injury is sought. In the case of a hand injury, the patient's hand dominance and occupation are determined. All patients with acute wounds should be assessed for malnutrition, diabetes, peripheral vascular disease, neuropathy, obesity, immune deficiency, autoimmune disorders, connective tissue diseases, coagulopathy, hepatic dysfunction, malignancy, smoking practices, medication use that could interfere with healing, and allergies. The local wound environment should be evaluated to determine the extent and complexity of injury, the tissues involved, the presence or absence of contamination by microorganisms or foreign bodies, and the degree of any damage related to previous irradiation or injury to surrounding tissues.

Gloves and a shielded mask are worn to protect the practitioner from exposure to body fluids. Gloves must be powder free, as well as latex free (to prevent allergic reactions to latex).¹ The wound is carefully examined, with particular attention paid to size, location, bleeding, arterial or venous insufficiency, tissue temperature, tissue viability, and foreign bodies. The possibility of damage to vessels, nerves, ducts, cartilage, muscles, or bones in proximity to the injury is assessed. X-rays and a careful motor and sensory examination may be required to rule out such coexisting injuries. While these tests are being performed, moist gauze should be applied to wounds. For thorough assessment of injuries, it may be necessary to probe ducts (e.g., the parotid duct or the lacrimal duct).

At this point, decisions must be made about acute wound care. The goal of acute wound management is a closed, healing wound that will result in the best functional and aesthetic outcome. In what follows, we address the key considerations in management of the acute wound, including anesthesia, choice of repair site (i.e., operating room or emergency department), debridement, irrigation, hemostasis, closure materials, timing and methods of closure, appropriate closure methods for specific wound types, dressings, adjunctive treatment (e.g., tetanus and rabies prophylaxis, antibiotics, and nutritional supplementation), postoperative wound care, and potential disturbances of wound healing. Finally, we briefly review the physiology of wound healing.

Wound Preparation

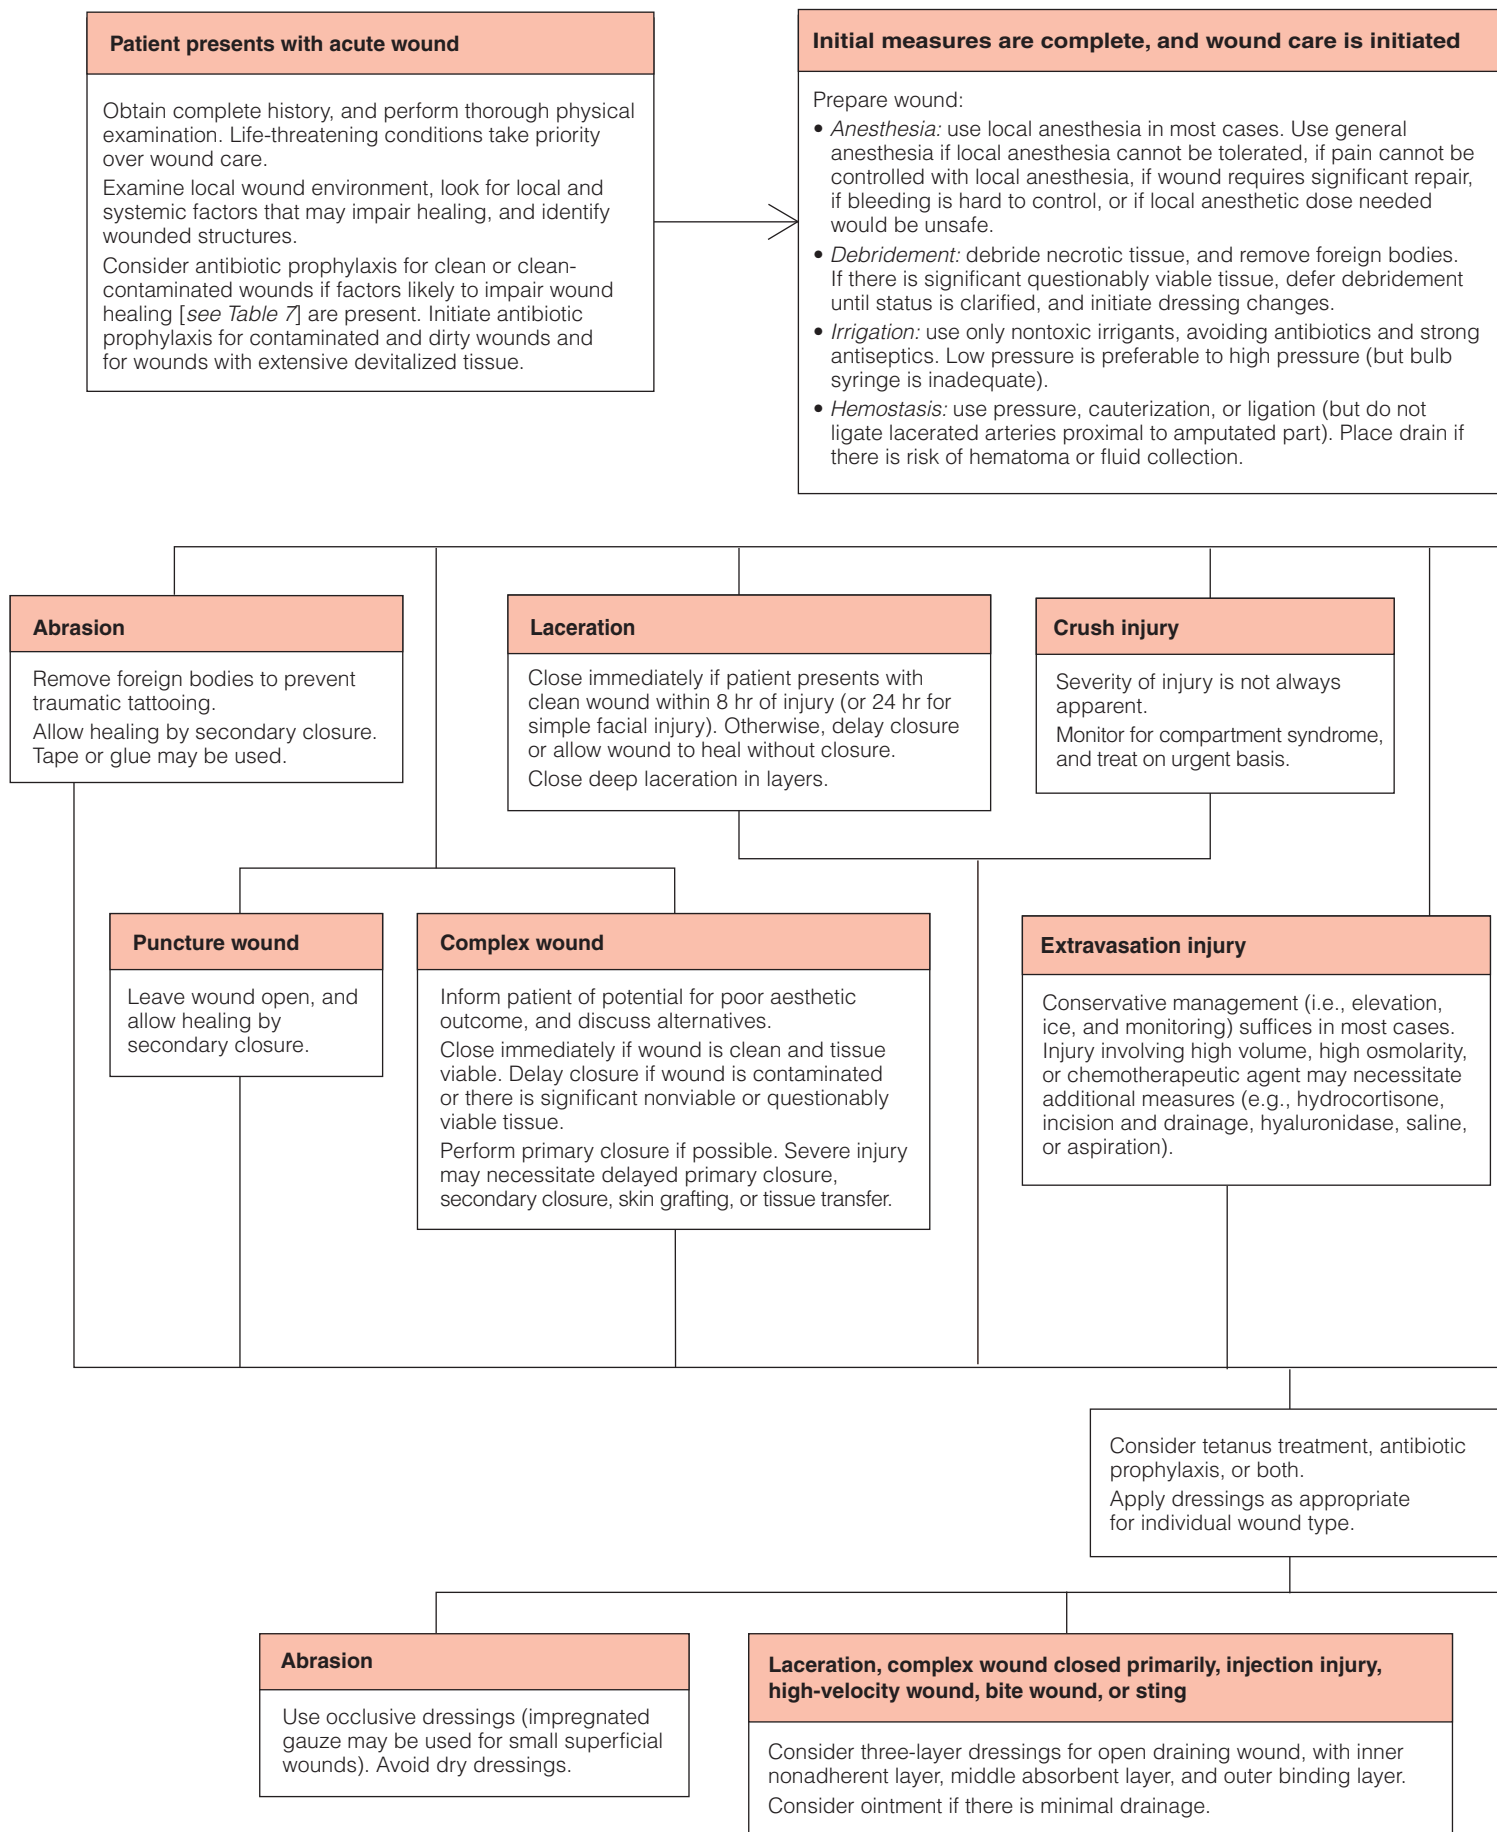

ANESTHESIA

Adequate general or local anesthesia, preceded by careful motor and sensory examination, must be instituted before examination and treatment of the wound can begin. General anesthesia in the OR is employed if the patient is unable to tolerate local anesthesia; adequate pain control cannot be achieved with a local block; the wound requires significant debridement, exploration, or repair; bleeding is difficult to control; or the local anesthetic dose required for adequate pain control exceeds the maximum dose that can be safely delivered. Local anesthesia is usually sufficient for debridement and closure of most small traumatic wounds. Often, the local anesthetic may be injected directly into wounded tissue. However, direct wound injection may be less reliable in inflamed or infected tissue or may distort important anatomic landmarks used to align wound edges. In these situations, regional nerve blocks directed at specific sensory nerves outside the injured field may be employed instead.

The main injectable anesthetics can be broadly divided into amides and esters [see Table 1]. (An easy way of remembering which category an agent belongs to is to recall that the amides all have two *Is* in their generic name, whereas the esters have only one.) Lidocaine, an amide, is the most commonly used local anesthetic. Its advantages include its rapid onset of action (< 2 minutes), its extended duration of action (60 to 120 minutes), its relative safety in comparison with more potent anesthetics (e.g., bupivacaine), and its availability in multiple forms (e.g., liquid, jelly, and ointment) and concentrations (e.g., 0.5%, 1.0%, and 2.0%). In addition, lidocaine rarely causes allergic reactions, whereas ester anesthetics (e.g., tetracaine) are metabolized to para-aminobenzoic acid, to which some persons are allergic. Cocaine, an ester, is an excellent local anesthetic for wounds in

Table 1 Common Injectable Anesthetics³

Amides	Esters
Lidocaine (Xylocaine)	Procaine (Novocain)
Bupivacaine (Marcaine)	Chloroprocaine (Nesacaine)
Mepivacaine (Carbocaine)	Tetracaine (Pontocaine)
Prilocaine (Citanest)	Benzocaine (multiple brands)
Etidocaine (Duranest)	Propoxycaine (Ravocaine)
Phenocaine	Cocaine
Dibucaine (Nupercainal)	
Ropivacaine (Naropin)	
Levobupivacaine (Chirocaine)	

Approach to Acute Wound Management

Wound is ready for closure

Select closure materials: sutures, tapes, staples, or adhesives.

Determine timing and methods of closure:

- *Immediate primary closure*: clean wound without contraindications to closure
- *Delayed primary closure*: contaminated wound, wound with questionably viable tissue, or patient who cannot tolerate immediate closure
- *Secondary closure (allowing wound to heal by itself)*: wound with contamination or contraindication to closure, patient who cannot tolerate closure, or wound for which closure is not needed for aesthetic result
- *Skin grafting*: large superficial wound
- *Tissue transfer*: large wound with exposed vital structure

Formulate specific closure approach suitable for individual wound type.

Injection injury

Wound appearance is often deceptively benign. Examine wound area carefully and obtain appropriate radiographs.

Treat aggressively with incision, wide exposure, debridement, and removal of foreign bodies.

Allow healing by secondary closure.

Bite wound

Take into account risks of rabies, bacterial and other viral infections, and envenomation.

Treat with exploration, irrigation, and debridement.

Close immediately if wound is clean and tissue viable. Delay closure if wound is contaminated or there is significant nonviable or questionably viable tissue.

Perform primary closure if possible. Severe injury may necessitate secondary closure, skin grafting, or tissue transfer.

Consider rabies treatment, rabies prophylaxis, or both.

High-velocity wound

Wound appearance is often deceptively benign; foreign bodies are frequently present. Examine wound area carefully and obtain appropriate radiographs.

Debride wound extensively and identify all injured tissue.

Avoid immediate primary closure. Perform delayed primary closure or allow healing by secondary closure.

Sting

Take into account risk of envenomation.

Symptoms may be local or systemic. Treatment is usually directed toward local symptoms. For systemic reactions, epinephrine, diphenhydramine, and supportive airway and BP care may be required.

Complex wound left open or closed after delay

Generally, use wet-to-dry dressings; use wet-to-wet dressings if wound bed contains tendons, arteries, nerves, or bone. Avoid compression dressings. Consider NPWT for large open wound.

Extravasation injury or crush injury

Avoid compression dressings.

mucous membrane (e.g., those in the nose or the throat). It is unique among local anesthetics in that it causes vasoconstriction, which helps reduce hemorrhage. Typically, cocaine is applied topically by soaking gauze or pledgets in a solution.

Vasoconstriction can also be produced by adding epinephrine to a local anesthetic, usually in a dilution of 1:100,000 or 1:200,000 (5 to 10 µg/ml). Through vasoconstriction, epinephrine prolongs the anesthetic agent's duration of action, allows a larger dose to be safely administered, and aids in hemostasis.² Traditionally, local anesthetics with epinephrine have not been used in finger and toe wounds, because of the theoretical risk of ischemia and tissue loss; however, these adverse effects have not yet been reported clinically or documented by any prospective studies.³

Local anesthetics can cause systemic toxicity when injected intravascularly or given in excessive doses. Manifestations of systemic toxicity begin with central nervous system effects (e.g., vertigo, tinnitus, sedation, and seizures) and may progress to cardiovascular effects (e.g., hypotension, cardiac conduction abnormalities, and cardiovascular collapse). Treatment for systemic toxicity is supportive, with oxygen, airway support, and cardiovascular bypass (if necessary) provided until the anesthetic has been metabolized by the liver. The maximum safe dose of lidocaine is 3 to 5 mg/kg without epinephrine and 7 mg/kg with epinephrine. Doses as high as 55 mg/kg have been used without toxicity for tumescent anesthesia in patients undergoing liposuction⁴; however, in this scenario, some of the anesthetic is aspirated by the liposuction, which means that the effective dose is lower. The lidocaine doses used for local wound injection should be substantially smaller than those used in liposuction. The maximum safe dose of cocaine is 2 to 3 mg/kg. To prevent local anesthesia from causing systemic toxicity, the recommended safe doses of the anesthetics should not be exceeded, and aspiration should be performed before injection into the wound to ensure that the agent will not be injected intravascularly.

The pain associated with injection of the local anesthetic can be minimized by using a small-caliber needle (27 to 30 gauge), warming the anesthetic, injecting the agent slowly, using a subcutaneous rather than an intradermal injection technique,⁵ providing counterirritation, buffering the anesthetic with sodium bicarbonate to reduce acidity (in a 1:10 ratio of sodium bicarbonate to local anesthetic),⁶ and applying a topical local anesthetic before injection. Topical local anesthetics (e.g., TAC [tetracaine, adrenaline (epinephrine), and cocaine] and EMLA [a eutectic mixture of lidocaine and prilocaine]) are as effective as injectable anesthetics when applied to an open wound.⁷ EMLA requires approximately 60 minutes to induce sufficient anesthesia for open wounds; TAC requires approximately 30 minutes.⁸ EMLA is more effective than TAC for open wounds of the extremity. Benzocaine 20% (in gel, liquid, or spray form) can also be used for topical anesthesia and is frequently employed before endoscopic procedures. It is poorly absorbed through intact skin but well absorbed through mucous membranes and open wounds. A 0.5- to 1-second spray is usually recommended, though even with a standardized spray duration, the delivered dose can vary considerably.⁹ A 2-second spray results in a statistically, though not clinically, significant increase in methemoglobin levels.¹⁰ Methemoglobinemia is a rare but life-threatening complication of benzocaine spray use. If symptoms of methemoglobinemia develop (e.g., cyanosis or elevated methemoglobin levels on cooximetry), prompt treatment with intravenous methylene blue, 1 to 2 mg/kg, is indicated.⁹

DEBRIDEMENT

Normal healing can proceed only if tissues are viable, if the wound contains no foreign bodies, and if tissues are free of exces-

sive bacterial contamination. To reduce the risk of infection in an acute wound, necrotic tissue and foreign bodies must be removed.¹¹ The wound and the surrounding local tissue must be exposed so that necrotic tissue can be identified and debrided. Hair may be trimmed with scissors or an electric clipper or retracted with an ointment or gel to facilitate exposure, debridement, and wound closure. Close shaving with a razor should be avoided, however, because it potentiates wound infections.¹² Clipping of eyebrows should also be avoided, both because the eyebrows may not grow back and because the hair is necessary for proper alignment.

Some wounds contain a significant amount of questionably viable tissue. If there is enough questionably viable tissue to preclude acute debridement, dressing changes may be initiated. When all tissue has been declared to be either viable or necrotic and when the necrotic tissue has been debrided surgically or by means of dressing changes, the wound can be closed.

Most foreign bodies are easily removed from wounds either by hand or via surgical debridement. Abrasion injuries or gunpowder explosions can cause small foreign body fragments to be embedded in and beneath the skin. These small foreign bodies are often difficult to extract but should be removed as soon after the injury as possible. Irrigation usually suffices for removal of loose foreign bodies, but surgical debridement with a small drill, a sharp instrument, or a brush may be required for removal of more firmly embedded foreign material. If the interval between injury and treatment exceeds 1 to 2 days, the wounds will begin to epithelialize and the embedded material will be trapped in the skin, resulting in traumatic tattooing.

IRRIGATION

After debridement of necrotic tissue and foreign bodies, the next step is irrigation of the wound. This may be accomplished by means of several different methods, including bulb syringe irrigation, gravity flow irrigation, and pulsatile lavage. These methods can be further divided into high-pressure (35 to 70 psi) and low-pressure (1 to 15 psi) delivery systems. High-pressure pulsatile lavage reduces bacterial concentrations in the wound more efficiently than low-pressure and bulb syringe irrigation do,¹³ but it also causes considerable disruption to soft tissue structure¹⁴ and results in deeper penetration and greater retention of bacteria in soft tissue than low-pressure lavage does.¹⁵ In general, low-pressure systems should be employed for acute wound irrigation, though merely running saline over a wound is of little value. To obtain continuous irrigation with pressures as low as 5 to 8 psi, one group recommended using a saline bag in a pressure cuff inflated to 400 mm Hg and connected to I.V. tubing with a 19-gauge angiocatheter.¹⁶

Only nontoxic solutions (e.g., 0.9% sterile saline, lactated Ringer solution, sterile water, and tap water) should be used for wound irrigation.¹⁷ Irrigation with an antibiotic solution appears to offer no advantages over irrigation with a nonsterile soap solution, and the antibiotic solution may increase the risk of wound-healing problems.¹⁸ Strong antiseptics (e.g., povidone-iodine, chlorhexidine, alcohol, sodium hypochlorite, and hydrogen peroxide) should not be placed directly into the wound, because they are toxic to the tissues and impede healing. The surrounding skin should be prepared with an antibacterial solution, and a sterile field created to limit contamination.

HEMOSTASIS

In most wounds, hemorrhage can be readily controlled with pressure, cauterization, or ligation of vessels. Lacerated arteries

proximal to amputated parts such as fingers or ears, however, should not be ligated, because an intact vessel is necessary for microsurgical replantation. Packing, wrapping, and elevating can help control hemorrhage temporarily. If necessary (though the need should be rare), a tourniquet may be applied to an injured extremity. Hemostasis prevents hematoma formation, which increases the risk of infection and wound inflammation. If there appears to be a potential risk of hematoma or fluid collection, drains should be placed. Although drains may help prevent accumulation of blood or serum in the wound, they are not a replacement for meticulous hemostasis. Drains facilitate approximation of tissues, particularly under flaps; however, they also tend to potentiate bacterial infections and should therefore be removed from the wound as soon as possible.¹⁹

As a rule, drains can be safely removed when drainage reaches levels of 25 to 50 ml/day. If a hematoma or seroma forms, the subsequent course of action depends on the size of the fluid collection. Small hematomas and seromas usually are reabsorbed and thus can be treated conservatively. Larger hematomas and seromas provide a significant barrier to healing, and treatment may require reopening the wound and placing drains. Intermittent sterile aspirations, followed by application of a compressive dressing, may be indicated for seromas. If this approach fails to eliminate the seroma, a drain may be reintroduced.

Wound Closure

MATERIALS

Once the appropriate preparatory measures have been taken (see above), the wound is ready to be closed. The first step is to choose the material to be used for wound closure. The materials currently available for this purpose include sutures, staples, tapes, and glues. Selection of the appropriate material is based on the type and location of the wound, the potential for infection, the patient's ability to tolerate closure, and the degree of mechanical stress imposed by closure. The selected material must provide wound edge approximation until the tensile strength of the wound has increased to the point where it can withstand the stress present.

The majority of wounds are closed with sutures. A suture is a foreign body by definition, and as such, it may generate an inflammatory response, interfere with wound healing, and increase the risk of infection. Accordingly, the number and diameter of sutures used to close a wound should be kept to the minimum necessary for coaptation of the edges.

Sutures are categorized on the basis of material used, tensile strength, configuration, absorbability, and time to degradation [see Table 2]. Suture material may be either natural or synthetic; natural fibers (e.g., catgut and silk) cause more intense inflammatory reactions than synthetic materials (e.g., polypropylene) do.²⁰ The tensile strength of suture material is defined as the amount of weight required to break a suture divided by the suture's cross-sectional area. It is typically expressed in an integer-hyphen-zero form, whereby larger integers correspond to smaller suture diameters (e.g., 3-0 sutures have a greater diameter and more tensile strength than 5-0 sutures do).²¹ Closure of acute wounds rarely requires sutures larger than 4-0. In terms of configuration, suture material may be composed either of a single filament or of multiple filaments. Multifilament suture material may be twisted or braided, and the interstices created by braiding may harbor organisms and

increase the risk of infection. Monofilament sutures hold knots less well than multifilament sutures, requiring five knots for security; multifilament sutures are easier to handle and require only three knots. With all sutures, the knots must be square to be secure and must be only tight enough to coapt the wound edges. To minimize foreign body bulk, buried suture knot ends should be cut right on the knot. In terms of absorbability, either absorbable or nonabsorbable sutures may be appropriate, depending on the situation. Absorbable sutures are generally used for buried sutures to approximate deep tissues (e.g., dermis, muscle, or fascia). Absorption of synthetic suture material occurs by hydrolysis and causes less tissue reaction than absorption of natural suture material, which occurs by proteolysis. Nonabsorbable sutures (e.g., those made of silk, nylon, polyester, or polybutester) are most commonly used for wounds in the skin, from where they will eventually be removed, or for wounds in deeper structures that require prolonged support (e.g., abdominal wall fascia, tendons, nerves, and blood vessels).

Staple closure is less expensive and significantly faster than suture closure, and it offers a slightly, though not significantly, better cosmetic outcome when used to close scalp wounds.^{22,23} Contaminated wounds closed with staples have a lower incidence of infection than those closed with sutures.²⁴ In addition, staple closure eliminates the risk that a health care provider will experience a needle stick, which is a particularly important consideration in caring for a trauma patient with an unknown medical history.

The tapes used for wound closure either are rubber-based or employ an acrylate adhesive. Rubber-based tapes (e.g., athletic tape) are a potential irritant to skin, degrade with exposure to heat, light, and air, and are occlusive, thereby preventing transepidermal water loss. Tapes that include acrylate adhesives (e.g., Micropore and Steri-Strip), however, are hypoallergenic, have a long shelf life, and are porous, thereby allowing water to evaporate.²⁵ Linear wounds in areas with little tension are easily approximated with tape alone, whereas wounds in areas where the skin is more taut (e.g., the extremities) generally require that tape skin closure be supplemented by dermal sutures. The use of tape alone is desirable when feasible, in that it spares the patient the discomfort associated with suture removal, prevents suture puncture scars, and avoids the emotional upset that may attend suture closure of small facial wounds on children.²⁵ Tape closure has some significant advantages: it immobilizes wound edges, permits early suture removal, is easy to perform and comfortable for the patient, leaves no marks on the skin, and yields a lower infection rate in contaminated wounds than suture closure does.²⁶ It also has a few disadvantages: patients may inadvertently remove the tapes, and wound edge approximation is less precise with tapes alone than with sutures. In addition, tape will not adhere to mobile areas under tension (e.g., the plantar aspects of the feet) or to moist areas (e.g., mucous membranes and groin creases), and wound edema can lead to blistering at the tape margins and to inversion of taped wound edges.

The use of tissue adhesives (e.g., octylcyanoacrylate) is a fast, strong, and flexible method of approximating wound edges. Compared with sutures, staples, and tapes, adhesives provide a faster closure and are essentially equivalent in terms of cosmetic outcome, infection rate, and dehiscence rate.²⁷ Adhesives can be used on most parts of the body and have been employed to close wounds ranging from 0.5 to 50 cm in length. Their advantages include reduced cost, ease of application, and the absence of any need for needles or suture removal; their major disadvantage is lack of strength.²⁸ They must not be applied to tissues within wounds but, rather, should be applied to intact skin at wound edges, where they serve to hold injured surfaces together. In addi-

Table 2 Types and Characteristics of Suture Material Used for Wound Closure

Suture Type	Material	Comment	Configuration	Method of Absorption	Tensile Strength at 2 Wk	Time to Degradation
Absorbable	Plain catgut (bovine intestinal serosa)	Natural; high tissue reactivity	Monofilament	Proteolysis	0%	10–14 days
	Chromic catgut (bovine intestinal serosa treated with chromic acid)	Natural; stronger, less reactive, and longer-lasting than plain catgut	Monofilament	Proteolysis	0%	21 days
	Fast-absorbing catgut	Natural	Monofilament	Proteolysis	0%	7–10 days
	Polyglytone 6211 (Caprosyn)	Synthetic	Monofilament	Hydrolysis	10%	56 days
	Glycomer 631 (Biosyn)	Synthetic	Monofilament	Hydrolysis	75%	90–110 days
	Polyglycolic acid (Dexon)	Synthetic	Monofilament/multifilament	Hydrolysis	20%	90–120 days
	Polyglactic acid (Vicryl)	Synthetic	Multifilament	Hydrolysis	20%	60–90 days
	Polyglyconate (Maxon)	Synthetic	Monofilament	Hydrolysis	81%	180–210 days
	Polyglycolide (Polysorb)	Synthetic	Multifilament	Hydrolysis	80%	56–70 days
	Polydioxanone (PDS)	Synthetic	Monofilament	Hydrolysis	74%	180 days
	Polyglecaprone 25 (Monocryl)	Synthetic	Monofilament	Hydrolysis	25%	90–120 days
	Polyglactin 910 (Vicryl RAPIDE)	Synthetic	Multifilament	Hydrolysis	0%	7–14 days
Nonabsorbable	Polybutester (Novafil)	Synthetic; low tissue reactivity; elastic; good knot security	Monofilament	—	High	—
	Nylon (Monosof, Dermalon, Ethilon)	Synthetic; low tissue reactivity; memory effect necessitates more knots	Monofilament	—	High	—
	Nylon (Nurolon)	Synthetic; low tissue reactivity	Multifilament	—	High	—
	Nylon (Surgilon)	Synthetic; silicon coated; low tissue reactivity	Multifilament	—	High	—
	Polypropylene (Prolene, Surgilene, Surgipro)	Synthetic; low tissue reactivity; slippery	Monofilament	—	High	—
	Polyethylene (Dermalene)	Synthetic	Monofilament	—	High	—
	Stainless steel	Lowest tissue reactivity of all sutures; poor handling; creates artifact on CT scan; moves with MRI	Monofilament/multifilament	—	Highest	—
	Cotton	Natural	Multifilament	—	—	—
	Silk (Sofsilik)	Natural; high tissue reactivity; good knot security	Multifilament	—	Poor	—
	Polyester (Dacron, Mersilene, Surgidac)	Synthetic; uncoated; high friction; low tissue reactivity; poor knot security	Multifilament	—	High	—
	Polyester (Ticron)	Synthetic; silicon coated; low tissue reactivity; good knot security	Multifilament	—	High	—
	Polyester (Ethibond)	Synthetic; polybutylate coated; low tissue reactivity; good knot security	Multifilament	—	High	—
	Polyester (Ethiflex, Tevdek)	Synthetic; Teflon coated; low tissue reactivity; good knot security	Multifilament	—	High	—

tion, they should not be used for wounds in mucous membranes, contaminated wounds, deep wounds, or wounds under tension. Adhesives are particularly useful for superficial wounds or wounds in which the deep dermis has been closed with sutures.

TIMING AND METHODS

Appropriate materials having been selected, the next issue to address is the timing of wound closure. The choices are (1) to close the wound at the time of initial presentation, (2) to delay closure until after a period of healing or wound care, and (3) to allow the wound to heal on its own. The best choice in a given situation depends whether the patient is stable and able to undergo wound repair, whether hemorrhage is under control, whether necrotic material has been adequately debrided and foreign bodies removed, whether and to what degree bacterial contamination is present, and what the expected aesthetic outcome of immediate closure might be in comparison with that of delayed closure or secondary healing.

The timing of wound closure determines the method that will be employed. The closure methods available include (1) primary closure by direct approximation; (2) delayed primary closure, in which the wound is closed after a healing period; (3) secondary closure, in which the wound is allowed to heal on its own; (4) skin grafting; and (5) the use of local or distant flaps. The ideal wound closure method would support the wound until it has nearly reached full strength (i.e., about 6 weeks), would not induce inflammation, would not induce ischemia, would not penetrate the epidermis and predispose to additional scars, and would not interfere with the healing process. Unfortunately, no existing method accomplishes all of these goals in all cases; some sort of compromise is virtually always necessary. In the acute wound setting, the simplest method that will achieve a good closure is preferred.

Primary closure provides optimal wound healing when two perpendicular, well-vascularized wound edges are approximated without tension. Closure should proceed from deep to superficial. The initial step is to identify landmarks and line up tissues, using skin hooks or fine forceps to keep from causing wound edge trauma. Although wound closure is usually a straightforward process, situations occasionally arise in which special caution is necessary. For instance, when a wound crosses tissues with different characteristics (e.g., at the vermilion border of the lip, the eyebrow, or the hairline of the scalp), particular care must be taken to align the damaged structures accurately. In the repair of soft tissue, it is critical to handle tissue gently with atraumatic surgical technique, to place sutures precisely, and to minimize tension and contamination.

The next step is tissue-specific repair, which may require the consultation of an experienced surgeon. Bone fractures are reduced and repaired with plates, rods, or external fixation devices. Muscle lacerations should be repaired because muscle is capable of a significant degree of regeneration. A completely lacerated muscle that is properly repaired recovers approximately 50% of its ability to produce tension and 80% of its ability to shorten, whereas a partially lacerated muscle that is properly repaired recovers approximately 60% of its ability to produce tension and 100% of its ability to shorten.²⁹ Tendon lacerations should be meticulously approximated to allow gliding and restore tensile strength. Either 4-0 multifilament polyester or monofilament polypropylene is a reasonable choice for muscle and tendon repair.³⁰ Early active mobilization promotes the restoration of tensile strength in muscles and tendons. Penetrating nerve trauma is treated with tension-free coaptation at the time of wound closure by primary repair or repair with a nerve graft or nerve tube. Epineurial coaptation is typically achieved by placing 8-0 to 10-0 monofilament

nylon sutures under loupe or microscope magnification. For ischemic or amputated tissues (e.g., an ear, a digit, or a limb), vessel repair is performed with 8-0 to 10-0 monofilament nylon sutures under magnification.

In subcutaneous fat, suture placement should be avoided whenever possible; if sutures in this location are absolutely necessary, they should be placed at the fat-fascia junction or the fat-dermis junction, not in fat alone. Fat cannot hold sutures by itself, and because it has a poor blood supply, suturing may lead to fat necrosis. The deeper fascial layers that contribute to the structural integrity of areas such as the abdomen, the chest, and the galea should be closed as a separate layer to prevent hernias, structural deformities, and hematomas.

At the skin level, the deep dermis is responsible for the strength of the acute wound closure. Deep dermal repair is performed with 4-0 absorbable suture material (e.g., polyglactin 910) and a cutting needle. The sutures are buried and placed 5 to 8 mm apart, with care taken to evert the skin edges. Buried dermal sutures are often used in conjunction with tapes (e.g., Steri-Strips), fine epidermal sutures, or adhesives to facilitate precise alignment. Skin edges should be coapted and everted with 4-0 to 6-0 nylon or polypropylene sutures placed in the superficial dermis and the epidermis. The distance between the sutures and the distance between the wound edge and the suture insertion point should be equal to the thickness of the skin (epidermis and dermis combined).

Several different skin suturing methods may be used, depending on the nature of the wound. Simple interrupted sutures are useful for irregular wounds. Vertical mattress sutures are good for either thick (e.g., scalp) or thin (e.g., eyelid) skin. Horizontal mattress sutures can lead to ischemia and thus must be applied loosely; they may look untidy early after repair, but they generally achieve good wound-edge eversion and long-term healing. Half-buried horizontal and vertical mattress sutures are used for flap edges to minimize ischemia. A continuous intradermal or subcuticular suture is easy to remove and relatively inconspicuous visually. A simple continuous suture should be used only for linear wounds; it is quick to place but tends to invert the wound edges. Flap tips should be sutured with a three-point method to prevent strangulation [see Figure 1]. For children, suture removal can be both emotionally and physically traumatic; accordingly, when suturing is employed for skin closure in a pediatric patient, the use of fast-absorbing suture material (e.g., plain catgut) or a pullout continuous subcuticular suturing method should be considered.

Primary direct approximation of wounds is not always indicated. In cases where obvious bacterial contamination is present, there is a substantial amount of questionably necrotic tissue, or the patient is unstable and unfit to undergo primary repair at the time of presentation, delayed primary closure is performed. Delayed primary closure involves direct approximation of wound edges after a period (usually 4 to 5 days) of wound hygiene. This closure method markedly diminishes the incidence of wound infection in patients with contaminated wounds.

Secondary closure, in which the wound is left open and allowed to heal on its own, is also sometimes chosen. Secondary closure depends on contraction of the surrounding tissue and epithelialization from the wound margins. When this approach is followed, caution and close observation are essential because the process of tissue contraction can sometimes lead to contracture, a pathologic scar deformity. Secondary closure can, however, yield acceptable results with specific wound types and at specific anatomic sites. With puncture wounds, for example, secondary closure is preferred because it diminishes the likelihood of infection. For both abrasions and puncture wounds, the functional and aesthetic

Figure 1 Shown is the method for inserting three-point sutures, along with three different applications of this method.

results of secondary closure are generally as good as or better than those obtained by primary or delayed primary closure. For wounds on anatomically concave surfaces (e.g., the medial canthal region, the nasolabial region, or the perineum), secondary wound healing generally yields excellent results.³¹ Secondary closure should also be considered for severely contaminated wounds, infected wounds, wounds with significant amounts of devitalized tissue, wounds with foreign bodies, lacerations older than 24 hours, wounds in patients who are in shock, and high-velocity wounds.³²

Occasionally, an acute wound is so large that neither primary nor secondary closure will suffice. Such wounds must be covered with skin grafts or transferred tissue (i.e., flaps) [see 3:3 *Open Wound Requiring Reconstruction* and 3:7 *Surface Reconstruction Procedures*]. Local or distant flaps must be considered for wounds that involve exposed bone denuded of periosteum, cartilage denuded of perichondrium, tendon denuded of paratenon, or nerve denuded of perineurium.

CLOSURE OF SPECIFIC TYPES OF WOUNDS

Wounds may be divided into 10 main types: abrasions, puncture wounds, lacerations, complex wounds, crush injuries, extravasation injuries, injection injuries, high-velocity wounds, bite wounds, and stings. In addition, the American College of Surgeons (ACS) has divided wounds into four major categories: clean, clean-contaminated, contaminated, and dirty [see Table 3]. The likelihood of infection after any surgical procedure is correlated with the ACS wound category: class I and II wounds have infection rates lower than 11%, whereas wounds in class IV have infection rates as high as 40%.³³

Abrasions

Abrasions are superficial wounds caused by scraping. They involve only the epidermis and a portion of the dermis and frequently heal secondarily within 1 to 2 weeks. If an abrasion is to be closed primarily, tape or glue may be used for epidermal approximation to prevent suture mark scars (which could be worse than the actual wound scar). In some patients who have experienced abrasion injuries (e.g., motorcycle accidents in which victims slide along asphalt) or blast injuries (e.g., firework explosions), small foreign body fragments become embedded in and beneath the skin, often

proving quite difficult to remove. Complete debridement of these embedded foreign bodies within 24 to 48 hours of injury is crucial in preventing so-called traumatic tattooing. In the early postinjury period, surgical debridement with a small drill, a sharp instrument, or a scrub brush may suffice for removal of the foreign material causing the traumatic tattoo; later, dermabrasion will be necessary.^{34,35} Once the wound is adequately debrided, semioclusive dressings should be applied to optimize epithelialization.

Puncture Wounds

Puncture wounds should be examined for foreign bodies, which must be removed when found. They are typically left open, treated with wound care, and allowed to heal by secondary intention. With

puncture wounds, secondary closure reduces the risk of infection and generally yields excellent aesthetic results.

Lacerations

The type of wound most commonly encountered by surgeons is a superficial or deep acute traumatic or surgical wound that is suitable for primary closure by direct approximation of the wound

edges. In this setting, the goal is to provide the best possible chance for uncomplicated healing. If the wound is to be closed, primary closure at the time of evaluation is preferred if it is feasible. As a rule, closure should be completed within 6 to 8 hours of the injury, though simple noncontaminated wounds of the face can be safely closed as long as 24 hours after the injury. Primary closure is generally desirable in that it eliminates the need for extensive wound care, allows the wound to heal more quickly, and minimizes patient discomfort. However, lacerations containing foreign bodies or necrotic tissue that cannot be removed by irrigation or debridement and lacerations with excessive bacterial contamination should not be closed primarily, nor should wounds in which hemostasis is incomplete. Hematomas,³⁶ necrotic tissue,³⁷ and foreign bodies³⁸ all promote bacterial growth and place a mechanical barrier between healing tissues.

Complex Wounds

The term complex wounds includes stellate wounds and those caused by degloving, avulsion, and mutilation. The goals of treatment include achieving closure within 6 to 8 hours of the injury, providing treatment in a manner consistent with the patient's general health, keeping bacterial counts at a low level, protecting tissues from desiccation, applying only nonnoxious agents, and supplying adequate permanent coverage. In addition, it is important to discuss with the patient the particular treatment difficulties posed by these wounds. Often, a patient with a complex wound must be treated in the OR under general anesthesia because the injury is extensive or because there is a need for exploration of tissues, removal of foreign bodies, and debridement of nonviable tissue.

Stellate wounds can be approximated with careful placement of interrupted and three-point sutures. Severely injured tissue may have to be removed as an ellipse, with the resulting defect closed.

Degloving refers to circumferential elevation of skin and fat from muscle; the skin flap created by this process rarely survives. In the acute setting, questionably viable flaps of tissue may be evaluated by administering fluorescein, up to 15 mg/kg I.V., and observing the flap for fluorescence under an ultraviolet lamp after 10 to 15 minutes have elapsed.³⁹ Viable flap tissue fluoresces green. Tissue that is determined to be devascularized, on the basis of either physical examination or fluorescein testing, should be debrided. If the viability of a tissue segment is in doubt, the segment may be sewn back into its anatomic location and allowed to define itself as viable or nonviable over time.

Large open wounds resulting from avulsion can be either left to heal by secondary intention or treated with delayed skin grafting.³²

Mutilating wounds caused by machinery (e.g., farm equipment) are often contaminated by a mixture of gram-positive and gram-negative organisms, though not always excessively so.⁴⁰ When such a wound is grossly contaminated, antibiotic therapy (preferably with an agent or combination of agents that offers broad-spectrum coverage) is indicated. Contaminated wounds closed with either tape or staples have a lower incidence of infection than those closed with sutures.^{24,26}

Crush Injuries

A notable feature of crush injury is that the severity of the wound is not always readily apparent. In many cases, no external laceration can be seen, even though deep tissue damage may be extensive. Ultrasonography or magnetic resonance imaging may help identify a hematoma that is amenable to evacuation.³² Deep tissue injury can lead to compartment syndrome and subsequent extremity loss. Early diagnosis is the key to successful treatment. Generally, the diagnosis can be made on the basis of physical signs and symptoms, including increasing pain that is out of proportion to the stimulus, altered sensation, pain on passive stretching of the affected muscle compartment, muscle weakness, and palpable tenseness of the compartment.⁴¹

If compartment syndrome is suspected, the intracompartmental pressure should be measured.⁴² If the intracompartmental pressure exceeds 30 mm Hg or if the so-called delta pressure (i.e., the diastolic blood pressure minus the intracompartmental pres-

Table 3 Classification and Infection Rates of Operative Wounds

Classification	Infection Rate (%)	Wound Characteristics
Clean (class I)	1.5–5.1	Atraumatic, uninfected; no entry of GU, GI, or respiratory tract
Clean-contaminated (class II)	7.7–10.8	Minor breaks in sterile technique; entry of GU, GI, or respiratory tract without significant spillage
Contaminated (class III)	15.2–16.3	Traumatic wounds; gross spillage from GI tract; entry into infected tissue, bone, urine, or bile
Dirty (class IV)	28.0–40.0	Drainage of abscess; debridement of soft tissue infection

sure) is less than or equal to 30 mm Hg, compartment syndrome is considered to be present. If clinical symptoms develop or the delta pressure is below 30 mm Hg, appropriate therapeutic measures should be taken, including restoration of normal blood pressure in the hypotensive patient, removal of all constrictive dressings, and maintenance of the limb at heart level.¹ If the delta pressure remains below 30 mm Hg, clinical symptoms and signs persist despite conservative measures, or both, fasciotomies should be performed within 6 hours.⁴¹ Hyperbaric oxygen therapy may also be beneficial in cases of crush injury with compartment syndrome in an extremity.⁴³ Compartment syndrome with muscle damage can also lead to rhabdomyolysis and renal failure. If an elevated serum creatine kinase concentration is reported, intravascular volume is stabilized, and urine flow is confirmed, a forced mannitol-alkaline diuresis should be initiated as prophylaxis against hyperkalemia and acute renal failure.⁴⁴

Extravasation Injuries

In some patients with arterial or venous catheters in place, a vessel may become occluded or a catheter dislodged from the intravascular space, leading to extravasation injury, whereby solutions or medicines are delivered into the interstitial space. The majority of acute extravasation injuries are quickly diagnosed and heal without complications, and in most cases, conservative management (i.e., elevation of the limb, application of ice packs, and careful monitoring) is adequate.⁴⁵ However, extravasation injuries involving high fluid volumes, high-osmolar contrast agents, or chemotherapeutic drugs can have more serious effects, resulting in skin ulceration and extensive soft tissue necrosis. Treatment of these injuries is not standardized; it may include conservative management, hydrocortisone cream, incision and drainage, hyaluronidase injection, saline injection, and aspiration by means of liposuction.^{45–47}

Injection Injuries

Wounds caused by injection of foreign materials (e.g., paint, oil, grease, or dirty water) can be severe. Injection injuries usually result from the use of high-pressure spray guns (600 to 12,000 psi) and

often occur on the nondominant hand.^{48,49} On initial examination, the injury may appear deceptively benign, with only a punctate entry wound visible; however, foreign material is often widely distributed in the deeper soft tissues. Radiographs are obtained to identify any fractures present and, in some cases, to determine the extent to which the injected material is distributed. Injection wounds must be treated aggressively with incision, wide exposure, debridement, and removal of foreign bodies to prevent extensive tissue loss and functional impairment. The functional outcome is determined by the time elapsed between injury and treatment and by the type of material injected. Oil-based paint is more damaging to tissues than water-based paint, oil, grease, water, or air.^{50,51}

High-Velocity Wounds

High-velocity wounds from explosions or gunshots cause extensive tissue damage as a consequence of the release of kinetic energy. Small entry wounds are common, but the seemingly benign appearance of such a wound often belies the actual severity of injury: the exit wound and interspace may contain large areas of ischemic and damaged tissue that affect critical structures (e.g., bone and blood vessels). Clothing and dirt may also be transmitted into the deep spaces. Radiographs may identify radiopaque foreign bodies (e.g., metal objects or pieces of leaded glass).⁵² Treatment of wounds created by high-velocity missiles involves extensive debridement and identification of injured tissue. Wounds should be left open to heal by secondary or delayed primary closure.³²

Bite Wounds

Treatment of bite wounds involves thorough exploration, irrigation, and debridement. X-rays must be obtained and wounds explored to evaluate the patient for fractures or open joint injuries. If a joint capsule has been violated, the joint must be thoroughly cleaned. Because of the infection risk, wounds may be allowed to heal by secondary or delayed primary closure; primary closure is also possible if thorough debridement is performed.³² Rabies prophylaxis treatment should be considered for patients who have been bitten by wild animals [see Adjunctive Wound Treatment, Rabies Prophylaxis, below].

Humans and nonvenomous animals Most human bite wounds are clenched fist wounds sustained by young men.⁵³ Human bite wounds are considered infected from the moment of infliction and must be treated with antibiotics.^{54,55} The antibiotic regimen should be selected on the basis of the bacterial species believed to be present. Common isolates from bite wounds includes *Streptococcus anginosus*, *Staphylococcus aureus*, *Eikenella corrodens*, *Fusobacterium nucleatum*, *Prevotella melaninogenica*, and *Candida* species.⁵³ To cover these species, a broad-spectrum antibiotic or combination of antibiotics (e.g., amoxicillin-clavulanate or moxifloxacin) should be administered.⁵³

Nonhuman primates can cause viral infection, most commonly with cercopithecine herpesvirus type 1. If left untreated, such infection can lead to meningoencephalitis, which carries a 70% mortality. Accordingly, acyclovir prophylaxis is recommended.⁵⁶

Wounds caused by cat bites or scratches are at high (80%) risk for infection, usually attributable to *Pasteurella multocida*. The aer-

obic and anaerobic organisms commonly found in cat-bite wounds are similar to those found in dog-bite wounds, and antibiotic prophylaxis with amoxicillin-clavulanate is appropriate.⁵⁷ Acute regional lymphadenitis after a cat scratch is known as cat-scratch disease and is caused by *Bartonella henselae*⁵⁸; it is treated by administering azithromycin.⁵⁹

Dog-bite wounds are at lower (16%) risk for infection than human-bite or cat-bite wounds and tend to be less severely contaminated with bacteria. The aerobic species commonly isolated from such wounds include *Pasteurella* (*P. canis*), *Streptococcus*, *Staphylococcus*, *Moraxella*, and *Neisseria*; common anaerobic isolates include *Fusobacterium*, *Bacteroides*, *Porphyromonas*, and *Prevotella*.⁵⁷ Prophylactic treatment with a combination of a β -lactam antibiotic with a β -lactamase inhibitor (e.g., amoxicillin-clavulanate) is appropriate.^{57,60}

Venomous animals *Snake bites.* Four types of poisonous snakes are native to the United States: the coral snakes (*Micrurus* and *Micruroides* species), from the family Elapidae, and three species of pit vipers, from the family Viperidae (rattlesnakes [*Crotalus* species], copperheads [*Agkistrodon tortorix*], and cottonmouths or water moccasins [*Agkistrodon piscivorus*]).⁶¹⁻⁶³ Pit vipers can be identified by the pit between the eye and the nostril on each side of the head, the vertical elliptical pupils, the triangle-shaped head, the single row of subcaudal plates distal to the anal plate, and the two hollow fangs protruding from the maxillae that produce the characteristic fang marks.⁶⁴ Coral snakes have rounder heads and eyes and lack fangs; they are identified by their characteristic color pattern, consisting of red, yellow, and black vertical bands.

Patients bitten by any of the pit vipers must be examined for massive swelling and pain, which, in conjunction with fang marks, suggest envenomation. Local pain and swelling typically develops within 30 minutes of the bite, though in some cases, these manifestations may take up to 4 hours to appear. Erythema, petechiae, bullae, and vesicles are sometimes seen. Severe envenomation may induce systemic reactions, including disseminated intravascular coagulation (DIC), bleeding, hypotension, shock, acute respiratory distress syndrome (ARDS), and renal failure. Patients bitten by coral snakes, on the other hand, show no obvious local signs when envenomation has occurred. Consequently, the physician must look for systemic signs, such as paresthesias, increased salivation, fasciculations of the tongue, dysphagia, difficulty in speaking, visual disturbances, respiratory distress, convulsions, and shock. These symptoms may not develop until several hours after the bite.

If signs or symptoms suggestive of envenomation are found, appropriate laboratory tests (hematocrit, fibrinogen level, coagulation studies, platelet count, urinalysis, and serum chemistries) should be ordered. Laboratory tests should be repeated every 8 to 24 hours for the first 1 to 3 days to determine whether envenomation is progressing. Severe envenomation can cause decreased fibrinogen levels, coagulopathy, bleeding, and myoglobinuria.

Treatment of venomous snake bites includes immobilization and elevation. If envenomation is suspected or confirmed, antivenin should be administered intravenously and as early as possible. Antivenins commonly used in the United States include Antivenin (Crotalidae) Polyvalent (ACP) (Wyeth Pharmaceuticals, Collegeville, Pennsylvania) and Crotalidae Polyvalent Immune Fab (Ovine) (CroFab; Protherics Inc., Nashville, Tennessee).⁶⁵ Fab antivenom (FabAV) is less allergenic and more potent than ACP and thus has largely supplanted it in the United States.^{65,66} Patients are treated with a loading dose of four to six vials of FabAV, followed by three two-vial maintenance doses at 6, 12, and 18 hours to prevent recurrence of symptoms. If symptoms

progress despite antivenin treatment, an additional four to six vials of FabAV are given twice more; if symptoms continue to progress, consideration should be given to using ACP. ACP remains the most effective antivenin for patients with coral snake bites and those who do not respond to FabAV. Before ACP is administered, the patient must be tested for sensitivity. The major complication of antivenin therapy is serum sickness. This complication occurs in approximately 50% to 75% of patients treated with ACP but in only 16% of those treated with FabAV.^{65,67}

Compartment syndrome is a rare but severe complication of a snake bite. Fasciotomy is sometimes required to relieve extremity compartment syndrome, but it is not necessary for prophylactic purposes. Tourniquets, incision and suction, cryotherapy, and electric shock treatment are of little value for snake bites and may increase complication rates. There is no clear evidence to support antibiotic prophylaxis in this setting.⁶⁴

Spider bites. The bites of most spiders found in the United States cause little to no wound or local reaction; however, there are three types that are capable of injecting venom with skin-penetrating bites. Brown recluse spiders (*Loxosceles reclusa*) can be identified by a violin-shaped dorsal mark. They are nocturnal, live in dark and dry places, and are found in the central and southern United States. The venom is a phospholipase enzyme that acts as a dermal toxin and almost always causes a local reaction.⁶⁸ Local signs and symptoms may be limited to minor irritation, though they may also progress to extreme tenderness, erythema, and edema. The onset of local signs and symptoms may be delayed for as long as 8 hours after a bite, and tissue necrosis may then develop over the following days to weeks. Systemic reactions may include mild hemolysis, mild coagulopathy, and DIC, though severe intravascular hemolytic syndrome and death have also been reported.^{68,69} Oral administration of dapsone (50 to 100 mg/day) to minimize tissue necrosis has been advocated by some⁷⁰; however, this treatment is of uncertain efficacy, and no prospective data currently support its use. Moreover, dapsone can cause a serious unwanted side effect, hemolytic anemia.⁶⁹ If systemic symptoms develop, systemic corticosteroid therapy and supportive measures are indicated. Brown recluse antivenin is not available in the United States.

Black widow spiders (*Latrodectus mactans*) can be identified by a red-hourglass ventral mark.⁶³ They live in dark, dry, and protected areas and are distributed widely throughout the continental United States. The venom is a neurotoxin that produces immediate and severe local pain. Local signs and symptoms include two fang marks, erythema, swelling, and piloerection.⁶⁸ Systemic reactions with neurologic signs may develop within 10 minutes and may include muscle pain and cramps starting in the vicinity of the bite, abdominal pain, vomiting, tremors, increased salivation, paresthesias, hyperreflexia, and, with severe envenomation, shock. Systemic symptoms may last for days to weeks. High-risk persons (e.g., those who are younger than 16 years, the elderly, pregnant women, hypertensive patients, or persons who continue to show symptoms despite treatment) may experience paralysis, hemolysis, renal failure, or coma. Treatment includes 10% calcium gluconate I.V. for relief of muscle spasm, methocarbamol or diazepam for muscle relaxation, and a single dose of antivenin. Antivenin causes serum sickness in as many as 9% of patients; consequently, its use is controversial except in cases where the patient is at high risk.⁷¹

Hobo spiders (*Tegenaria agrestis*) can be identified by their long hairy legs and a cephalothorax that is marked by two stripes and butterfly markings dorsally and two stripes ventrally. Found

throughout the northwestern United States, they live in low places and build funnel-shaped webs in dark spaces. Hobo spiders have been reported to inflict painful bites that lead to wound ulceration, dermonecrosis, and a persistent headache, though the accuracy of such reports has been debated.^{69,72,73} A slow-healing ulcer that leaves a central crater has been described. Treatment consists of local wound care.

Stings

Scorpions Stings from most of scorpion species found in the United States cause only limited local reactions that can be managed conservatively; however, stings from *Centruroides sculpturatus*, which is found in California and many southern states, may be more severe. *Centruroides* has a sting that causes envenomation with a neurotoxin. Erythema, edema, and ecchymosis at the site of the sting are evidence that envenomation did not take place. Instead, envenomation is indicated by an immediate and intense burning pain at the wound site.⁷⁴ The initial local pain may then be followed by systemic symptoms such as muscle spasm, excess salivation, fever, tachycardia, slurred speech, blurry vision, convulsions, or death.⁶⁸ Treatment consists of icing and elevation of the wounded area, followed by administration of barbiturates for control of neuromuscular activity and institution of supportive therapy with antihistamines, corticosteroids, and analgesics.⁷⁴

Centipedes Centipedes are slender, multisegmented, and multilegged arthropods that range in size from 1 to 30 cm and in color from bright yellow to brownish black. The first pair of legs are modified into sharp stinging structures that are connected to venom glands. Centipedes prefer dark, damp environments and may be found throughout the southern United States. Local symptoms associated with centipede stings include pain, erythema, edema, lymphangitis, lymphadenitis, weakness, and paresthesia. Skin necrosis may occur at the envenomation site. Systemic symptoms may include anxiety, fever, dizziness, palpitations, and nausea.⁷⁵ Treatment consists of symptomatic pain control, infiltration of local anesthetics, administration of antihistamines, and local wound care.⁷⁵

Hymenoptera The order Hymenoptera includes wasps, bees, and ants. Wasps, which are found across the United States, live in small colonies and may attack in groups when provoked. Honeybees (*Apis mellifera*) and bumblebees (*Bombus* species), also found across the United States, are generally docile and rarely sting unless provoked. Africanized honeybees (*Apis mellifera scutellata*, also referred to as killer bees), found primarily in the southwestern states, are far more aggressive than other bees. Fire ants (*Solenopsis invicta* and *Solenopsis richteri*) are wingless, ground-dwelling arthropods that are found in many southern states and that attack in an aggressive swarm.

Although Hymenoptera stingers are small, they can evoke severe local and systemic reactions. The local response to a Hymenoptera sting is a painful, erythematous, and edematous papule that develops within seconds and typically subsides in 4 to 6 hours. Some stingers are barbed and must be removed with a scraping, rather than pinching, motion to prevent the injection of more venom. Systemic reactions occur in about 5% of the population and may lead to anaphylaxis with syncope, bronchospasm, hypo-

tension, and arrhythmias. Wounds and local reactions are treated with ice, elevation, and analgesics. Systemic reactions are treated with subcutaneous epinephrine, diphenhydramine, and supportive airway and blood pressure care.⁶⁸ Persons with a history of systemic reactions to insect stings should carry epinephrine kits.

DRESSINGS FOR SPECIFIC TYPES OF WOUNDS

Generally, the functions of a wound dressing include protection, antiseptics, pressure, immobilization, debridement, provision of a physiologic environment, absorption, packing, support, information, comfort, and aesthetic appearance. More specifically, the functions of a dressing should be tailored to the wound type, and the purpose of the dressing must be carefully considered before application.

With sutured wounds, dressings are required only until drainage from the wound ceases. With nondraining wounds, dressings may be removed after 48 hours, by which time epithelial cells will have sealed the superficial layers of the wound. An alternative method of treating minimally draining incisional wounds is to apply an antibacterial ointment [see Adjunctive Wound Treatment, Topical Antimicrobials, *below*]. Such ointments are occlusive and maintain a sterile, moist environment for the 48 hours required for epithelialization. In anatomic areas that are difficult to dress (e.g., the scalp), it may be reasonable to forgo a dressing and simply apply ointments or allow a scab to form on the wound surface. Operative incisional wounds are also sometimes covered with an occlusive dressing to optimize epithelialization [see Abrasions, *above*]. Some of these dressings are transparent, allowing observation of the wound. The disadvantage of occlusive dressings is their limited absorptive capacity, which allows drainage from the wound to collect underneath.

Complex Wounds

Abrasions
Abrasions heal by epithelialization, which is accelerated by the warm, moist environment created by an occlusive dressing.^{76,77} Such an environment not only promotes epithelialization but also enhances healing, both because of the moisture itself and because of the low oxygen tension that promotes the inflammatory phase.⁷⁸ A variety of dressings are suitable for treatment of abrasions, including biologic dressings, hydrogels, hydrocolloids, and semipermeable films. These dressings need not be changed as long as they remain adherent. Small, superficial wounds also heal readily when dressed with impregnated gauze dressings (e.g., Xeroform and Scarlet Red [Kendall, Mansfield, Massachusetts]), which allow exudates to pass through while maintaining a moist wound bed.⁷⁸ These less adherent dressings must be changed more regularly.⁷⁹

Dry dressings (e.g., gauze) should be avoided with abrasions because they facilitate scab formation. Scabs slow epithelialization, in that advancing cells must enzymatically debride the scab-wound interface in order to migrate.⁸⁰ Wounds covered with a scab also tend to cause more discomfort than wounds covered with occlusive dressings.

For complex wounds containing questionably necrotic tissue, foreign bodies, or other debris that cannot be removed sharply, wet-to-dry dressings are effective, simple, and inexpensive. A single layer of coarse wet gauze is applied to a wound, allowed to dry over a period of 6 hours, and removed. Necrotic tissue, granulation tissue, debris, and wound exudate become incorporated within the gauze and are removed with the dressing. The disadvantages of wet-to-dry dressings are pain and damage to or removal of some viable tissue. If the wound bed contains tendons, arteries, nerves, or bone, wet-to-wet dressings should be used to prevent desiccation of these critical structures.

Wet-to-wet dressings, which are not allowed to dry, cause less tissue damage than wet-to-dry dressings but do not produce as much debridement. Most wet-to-wet dressings are kept moist with saline. Wounds with significant bacterial contamination may be treated with dressings that contain antibacterial agents (e.g., mafenide, silver sulfadiazine, silver nitrate, or iodine).

Biologic and semipermeable films also maintain a moist wound bed, but they are difficult to use on deep or irregular wounds and wounds with a great deal of drainage. Consequently, wet-to-wet dressings with agents such as silver sulfadiazine are often used for these types of wounds. Enzymatic agents can debride wounds effectively and are a reasonable alternative to wet-to-dry or wet-to-wet dressings for wounds that contain necrotic tissue.⁸²

Lacerations

For sutured deep wounds, the specific purposes of a dressing are to prevent bacterial contamination, to protect the wound, to manage drainage, and to facilitate epithelialization. Dressings used on such wounds usually consist of three basic layers. The inner (contact) layer is chosen to minimize adherence of the dressing to the wound and to facilitate drainage through itself to the overlying layers. Common choices for this layer include fine-mesh gauze, petrolatum gauze, Xeroform or Xeroflo (Kendall, Mansfield, Massachusetts) gauze, and Adaptic (Johnson & Johnson, New Brunswick, New Jersey). These substances should be applied only as a single layer; in multiple layers, they become occlusive. The middle layer is chosen for absorbency and ability to conform to shape of the wound area. It is usually composed of fluffs, Kerlix (Kendall, Mansfield, Massachusetts), or wide-mesh gauze, all of which facilitate capillary action and drainage.⁸¹ The middle layer must not be allowed to become soaked, because if it is, exudate will collect on the wound surface, and maceration and bacterial contamination may occur. The outer (binding) layer serves to secure the dressing. Common choices for this layer include Kling (Johnson & Johnson, New Brunswick, New Jersey), ACE bandages (BD Medical, Franklin Lakes, New Jersey), and Coban (3M, St. Paul, Minnesota).

Table 4 Recommendations for Tetanus Immunization^{89,90}

Tetanus Immunization History	Tt*	TIG
Unknown	Yes	Yes
> 10 yr since last booster	Yes	Yes
≥ 5 and ≤ 10 yr since last booster	Yes	No
< 5 yr since last booster	No	No

Note: Tetanus toxoid (Tt) and tetanus immune globulin (TIG) should be administered with separate syringes at different anatomic sites. Tetanus and diphtheria toxoids are contraindicated for the wounded patient if there is a history of a neurologic or severe hypersensitivity reaction after a previous dose. Local side effects alone do not preclude continued use. If a systemic reaction is suspected of representing allergic hypersensitivity, immunization should be postponed until appropriate skin testing is performed. If a contraindication to a Tt-containing preparation exists, TIG alone should be used.

*For patients younger than 7 years, diphtheria-tetanus-pertussis vaccine (DTP) (or tetanus and diphtheria toxoids, if pertussis vaccine is contraindicated) is preferable to Tt alone. For patients 7 years of age or older, Tt alone may be given.

Some wounds are difficult to dress and require special consideration. For wounds with flaps or questionably viable tissue, compression dressings should not be used, because they may cause ischemia. Wounds that cross joints are best dressed with plaster splints for temporary immobilization; semipermeable films are flexible and may also be used in this setting. Wounds with high levels of exudates may be dressed with hydrocolloids, hydrogels, or alginates.⁷⁸ For large or irregular wounds, negative-pressure wound therapy (NPWT) with the VAC system (Kinetic Concepts Inc., San Antonio, Texas) is recommended; VAC dressings conform well and remain adherent. Additionally, NPWT uses subatmospheric pressure to remove excess wound fluid, stimulates the formation of granulation tissue, improves peripheral blood flow and tissue oxygenation, and reduces the size of the wound.^{83,84} Use of the VAC system is contraindicated in wounds with exposed blood vessels or bowel.

Adjunctive Wound Treatment

PROPHYLACTIC SYSTEMIC ANTIBIOTICS

For most wounds, antibiotic prophylaxis is not indicated. When it is called for, the agent or agents to be used should be selected on the basis of the bacterial species believed to be present. The anatomic location of a wound may also suggest whether oral flora, fecal flora, or some less aggressive bacterial contaminant is likely to be present. Gram staining can provide an early clue to the nature of the contamination. Ultimately, the choice of a prophylactic antibiotic regimen is based on the clinician's best judgment regarding which agent or combination of agents will cover the pathogens likely to be present in the wound on the basis of the information available.

As a rule, clean and clean-contaminated wounds are adequately treated with irrigation and debridement. There are, however, some local factors (e.g., impaired circulation and radiation injury) and systemic factors (e.g., diabetes, AIDS, uremia, and cancer) that increase the risk of wound infection; in the presence of any of these factors, prophylactic antibiotics should be considered. In addition, prophylactic antibiotics should be given to patients with extensive injuries to the central area of the face (to prevent spread of infection through the venous system to the meninges), patients with valvular disease (to prevent endocarditis), and patients with prostheses (to reduce the risk of bacterial seeding of the prosthesis). Lymphedematous extremities are especially prone to cellulitis, and antibiotics are indicated whenever such extremities are wounded.

Contaminated and dirty wounds are associated with a higher risk of infection and are therefore more likely to necessitate antibiotic prophylaxis. Human bite wounds, mammalian bite wounds, and wounds contaminated with dirt, bodily fluids, or feces are all prone to infection and must be treated with antibiotics.^{54,55} Prophylactic administration of a combination of a β -lactam antibiotic with a β -lactamase inhibitor (e.g., amoxicillin-clavulanate) is appropriate.^{57,60} Antibiotic prophylaxis is also indicated for mutilating wounds with extensive amounts of devitalized tissue. Such wounds are often contaminated by a mixture of gram-positive organisms and gram-negative organisms.⁴⁰ When antibiotics are indicated for these injuries, broad-spectrum coverage is appropriate.

TOPICAL ANTIMICROBIALS

Topical antimicrobials (e.g., antibiotic ointments, iodine preparations, and silver agents) are commonly used to prevent wound infection. Application of mupirocin ointment to a clean surgical

wound before an occlusive dressing does not reduce the infection rate and may promote antibiotic resistance.⁸⁵ For uncomplicated traumatic wounds, however, application of bacitracin and neomycin ointment results in a significantly lower infection rate than application of petrolatum.⁸⁶ Neomycin-containing ointments reduce bacterial counts in partial-thickness wounds in animals, but many other over-the-counter antibiotic ointments are not effective at reducing bacterial counts in wounds.⁸⁷

Wounds contaminated by bacteria can be treated with dressings that contain antibacterial agents such as mafenide, silver nitrate, silver sulfadiazine, or iodine. Mafenide penetrates eschar well, but it can cause pain and has the potential to induce metabolic acidosis through inhibition of carbonic anhydrase. Silver has microbicidal effects on common wound contaminants and may also be effective against methicillin-resistant *S. aureus* (MRSA).⁸⁴ Silver nitrate does not cause pain, but it can cause hypochloremia, and it stains fingernails and toenails black. Silver sulfadiazine is frequently used because of its broad antibacterial spectrum, its relatively low side effect profile (transient leukopenia is occasionally seen), and its ability to maintain a moist wound environment (thereby speeding healing and epithelialization).⁸⁸

TETANUS PROPHYLAXIS

Tetanus is a nervous system disorder that is caused by *Clostridium tetani* and is characterized by muscle spasm. In the past, wounds were classified as either tetanus-prone or non-tetanus-prone on the basis of their severity. It is now clear, however, that wound severity is not directly correlated with tetanus susceptibility; tetanus has been associated with a wide variety of injury types over a broad spectrum of wound severity.⁸⁹ Accordingly, all wounds, regardless of cause or severity, must be considered tetanus prone, and the patient's tetanus immunization status must always be considered. Tetanus wound prophylaxis should be provided as appropriate [see Table 4].^{89,90}

RABIES PROPHYLAXIS

Rabies is an acute progressive encephalitis that is caused by viruses from the family Rhabdoviridae. The rabies virus can be transmitted by any mammal, but viral reservoirs are found only in carnivores and bats. In North America, raccoons, skunks, bats, and foxes are the animals most commonly responsible for transmission.⁹¹ Bite wounds in which the animal's saliva penetrates the dermis are the most common cause of exposure.

Postexposure treatment consists of wound care, infiltration of rabies immune globulin into the wound, and administration of vaccine.^{91,92} Wound care involves washing with soap and water, as well as the use of iodine- or alcohol-based virucidal agents.⁹³ Guidelines for postexposure prophylaxis have been established [see Table 5]. The vaccination regimen is determined by the patient's previous vaccination status [see Table 6].

Postoperative Wound Care

Closed wounds should be kept clean and dry for 24 to 48 hours after repair. Epithelialization begins within hours after wound approximation and forms a barrier to contamination. Gentle cleansing with running water will help remove bacteria and crusting. The patients should not place tension on the wound or engage in strenuous activity until the wound has regained sufficient tensile strength. In the first 6 weeks after repair, the wound's tensile strength increases rapidly; after this period, tensile strength increases more slowly, eventually reaching a maximum of 75% to 80% of normal skin strength [see Figure 2].

Table 5 Recommendations for Postexposure Rabies Prophylaxis⁹¹⁻⁹³

Animal Type	Animal Disposition and Evaluation	Prophylaxis
Dogs, cats, ferrets	If animal is healthy and available, it is confined for 10 days of observation	Start vaccination if animal exhibits rabies symptoms*
	If animal is rabid or suspected of being rabid, no observation is indicated	Provide immediate vaccination
	If animal's rabies status is unknown, consultation is indicated	Consult public health official
Bats, skunks, raccoons, foxes, bobcats, coyotes, mongooses, and most carnivores	Animal is regarded as rabid unless brain laboratory tests are negative	Provide immediate vaccination unless brain laboratory tests are negative
Livestock, small rodents (e.g., squirrels, chipmunks, rats, hamsters, gerbils, guinea pigs, and mice), large rodents (e.g., woodchucks and beavers), rabbits, hares, and other mammals	Each case is considered individually; rabies reported in large rodents in some areas	Consult public health officials; almost never require antirabies treatment

*If the isolated animal shows symptoms of rabies, postexposure prophylaxis is started immediately, and the animal is euthanized for laboratory testing. Vaccination prophylaxis is stopped if laboratory tests are negative for rabies.

Wounds at risk for infection should be assessed by a medical provider within 48 hours of care. In addition, the patient should be taught to look for signs of infection (e.g., erythema, edema, pain, purulent drainage, and fever).

The timing of suture or staple removal is determined by balancing the requirements for optimal cosmesis against the need for wound support. On one hand, it is clear that for optimal cosmesis, sutures should be removed early, before inflammation and epithelialization of suture tracts. An epithelialized tract will develop around a suture or staple that remains in the skin for longer than 7 to 10 days; once the suture or staple is removed, the tract will be replaced by scar.⁹⁴ On the other hand, it takes a number of weeks for the wound to gain significant tensile strength, and early removal of wound support can lead to dehiscence of wounds that are under substantial tension. Early suture removal is warranted for some wounds. For example, sutures in aesthetically sensitive areas (e.g., the face) may be removed on day 4 or 5, and sutures in areas under minimal tension (e.g., in wounds parallel to skin tension lines) may be removed on day 7. Sutures in wounds subject to greater stress (e.g., wounds in the lower extremities or the

trunk) should remain in place longer, as should sutures in wounds sustained by patients who have a condition that hinders healing (e.g., malnutrition). In such cases, suture-mark scars are considered acceptable. The appropriate method of removing a suture is first to cut it, then to pull on the knot parallel to or toward, rather than away from, the wound.

After suture removal, numerous methods are employed to minimize unsightly scar formation. The cosmetic outcome of a scar is largely determined by the nature and severity of the wound, which are outside the surgeon's control. The greatest impact a surgeon can have on cosmetic outcome is derived from providing meticulous care when the acute wound is initially encountered. Postoperative wound care measures employed to optimize cosmetic outcome include massage, the use of silicone bandages or pressure garments, and the application of lotions. These interventions appear to help, but prospective trials are needed to confirm their efficacy and establish treatment guidelines. The healing wound is fragile, and topical application of ointments to achieve an improved scar appearance may actually achieve the opposite result. For example, vitamin E, which is commonly applied to healing wounds, can induce contact dermatitis and cause scars to look worse.⁹⁵

Table 6 Recommendations for Postexposure Rabies Vaccination⁹¹⁻⁹³

Vaccine	Dosage	
	No Previous Vaccination	Previous Vaccination
Human rabies immune globulin (HRIG)	Full dose of 20 IU/kg infiltrated around wound(s) at initial presentation; use separate syringe and anatomic site from vaccine	Not administered
Human diploid cell vaccine (HDCV), rabies vaccine adsorbed (RVA), or purified chick embryo cell vaccine (PCECV)	1.0 ml IM on days 0, 3, 7, 14, and 28*	1.0 ml IM on days 0 and 3*

*Vaccine administration site for adults is the deltoid; for children, the anterolateral thigh may be used. To prevent sciatic nerve injury and reduce adipose depot delivery, the gluteus is never used.

Factors That May Hinder Wound Healing

Despite a surgeon's best efforts, healing does not always occur in an undisturbed fashion: sometimes, a closed wound dehisces. If the dehiscence is sudden, the wound is clean, and only skin and superficial tissues are involved, then the wound should be reclosed, and the cause of the dehiscence should be corrected if possible. If the dehiscence is slow and the wound is contaminated or infected, then the wound should be allowed to heal secondarily, with dressing changes and scar revision to be performed at a later date.

There are a number of local and systemic factors [see Table 7] that can interfere with wound healing (see below). Accordingly, it is essential for clinicians to be aware of and knowledgeable about these factors and, whenever possible, to take appropriate measures to improve the chances for optimal healing. The use of nutrients and growth factors to stimulate wound healing may be considered; this measure is currently the subject of extensive research.

Figure 2 The tensile strength of skin wounds increases rapidly for approximately 6 weeks after wounding; it then continues to increase slowly for 6 to 12 months after wounding, though it never reaches the tensile strength of unwounded tissue. Collagen is remodeled and replaced with highly cross-linked collagen along tissue stress lines. The process of collagen replacement and scar remodeling continues for years.

LOCAL FACTORS

Tension

Tension—whether from inherent skin tension, poor surgical technique, movement of joints, or inadequate wound support—may lead to separation of wound edges. It should be minimized by undermining the wound edges during closure to allow easy coaptation. Tissue ellipses from complex wound edges should be kept as narrow as possible and should be created along relaxed skin tension lines. Adequate support of the wound after suture removal is critical; many surgeons keep tapes (e.g., Steri-Strips) over a wound for 3 weeks, until the strength of the wound equals that of the deep sutures and tapes. Wounds over joints should be splinted to reduce tension.

Foreign Body

All foreign bodies that contaminate a wound should be removed at the time of initial debridement and before wound closure. Retained foreign bodies may cause failed healing, infection, or traumatic tattooing. Iatrogenic foreign bodies may also interfere with wound healing and promote infection. Suture material is a foreign body; thus, the number and size of sutures placed in a wound should be kept to the minimum necessary for coaptation of the wound edges.

Infection

All traumatic wounds are contaminated and should therefore be irrigated to remove organisms. Infection occurs when bacteria are too numerous ($>10^5$ organisms/g tissue) or virulent for local tissue defenses to be able to control them.⁹⁶ As noted [see Adjunctive Wound Care, Prophylactic Antibiotics, *above*], local factors (e.g., impaired circulation and radiation injury) increase the risk of infection, as do various systemic diseases (e.g., diabetes, AIDS, uremia, and cancer). Wound cultures should be obtained, and broad-spectrum antibiotic therapy should be started when infection is diagnosed. The antibiotic regimen is adjusted on the basis of culture results and sensitivities.

Ischemia

Ischemic wound tissue readily becomes infected and therefore must be debrided. Tissue with dermal edges that do not bleed or

that show no perfusion on fluorescein testing is ischemic. Questionably viable tissue should be monitored closely and debrided when declared nonviable.

Hematoma and Seroma

Hematomas and seromas increase the risk of infection and the likelihood of wound dehiscence. To prevent their formation, hemostasis at the time of wound closure must be meticulous, and bleeding diatheses must be corrected. Because the rubbing of wound edges against one another is associated with the formation of hematomas and seromas, wound edge movement should be minimized and immobilization employed as necessary. Wounds at significant risk for hematoma or seroma formation should be closed over a drain.

Large hematomas or seromas that are recognized early, before infection develops, should be evacuated, and the wound should be reclosed. Small hematomas or seromas can usually be treated conservatively until they are reabsorbed, but close observation is required. If a hematoma or seroma is not recognized until late, when infection has already set in, the wound should be opened, drained, and allowed to heal secondarily; scar revision may be carried out at a later point.

Trauma

Tissue injury is obviously associated with external trauma, but it can also be iatrogenic. Rough handling of tissue edges with forceps produces minute crush injuries, which promote wound infection. It is preferable to handle wound edges with hooks, using gentle surgical technique.

Edema

Edema results from the accumulation of fluid in the interstitial space. It may occur as an acute process, in which tissue injury leads to histamine release, leaky capillaries, and inflammation, or as a chronic process, in which venous insufficiency, lymphatic insufficiency, and a low plasma oncotic pressure may cause fluid to collect in the interstitium. In both cases, edema raises tissue pressure and inhibits perfusion and healing. The proteinaceous and fibrin-rich fluid also forms clot and fibrous tissue, which hinder the supply of oxygen and inflammatory cells.⁹⁷ Clearance of wound edema is necessary for healing and may be successfully accomplished by means of compression therapy⁹⁸ or NPWT with a VAC device.⁸³

Table 7 Local and Systemic Factors That Impair Wound Healing

Local Factors	Systemic Factors
Tension	Inherited connective tissue disorders
Foreign body	Hypothermia
Infection	Oxygen
Ischemia	Tobacco smoking
Hematoma and seroma	Malnutrition
Edema	Jaundice
Irradiation	Age
	Diabetes mellitus
	Uremia
	Steroids
	Chemotherapeutic agents
	Other drugs

Irradiation

Irradiation damages the skin and can cause wounds to heal slowly. It also induces chronic skin changes: previously irradiated tissues demonstrate delayed healing when wounded.⁹⁹ Irradiated tissue is characterized by a thickened and fibrotic dermis, a thin epidermis, pigment changes, telangiectasia, decreased hair, and increased dryness (as a consequence of damage to sebaceous and sweat glands). The microvasculature of the skin is obliterated, leading to tissue ischemia and impaired healing. Keratinocytes, which are necessary for wound epithelialization, exhibit impaired mitotic ability and slow progressive desquamation (as a consequence of their superficial location and high replication rate).⁹⁷ Collagen bundles become edematous and fibrotic. Fibroblasts, which are necessary for collagen synthesis, also show diminished migration and proliferation.¹⁰⁰

Because irradiated skin is irreversibly damaged, tissue transfer may be required for repair of wounds in areas subjected to radiation. Vitamin A supplementation can lessen the adverse effects of irradiation on wound healing.¹⁰¹

SYSTEMIC FACTORS

Inherited Connective Tissue Disorders

Several inherited connective tissue disorders are known to interfere with normal wound healing. Ehlers-Danlos syndrome exists as multiple types that exhibit certain differences, but in general, the syndrome leads to deficient collagen cross-linking, which results in lax and fragile skin, lax joints, and impaired wound healing. For example, an Ehlers-Danlos patient who undergoes an elective hernia repair or facelift may have a poor outcome as a consequence of deficient collagen formation and poor wound healing.^{102,103} Osteogenesis imperfecta is a procollagen formation disorder that is clinically manifested by brittle bones, increased laxity of ligaments and skin, bone deformities, and impaired wound healing.¹⁰⁴ Marfan syndrome is an autosomal dominant disorder characterized by deficient synthesis of fibrillin, which is a key component in elastin formation. Patients with this syndrome have long extremities and hyperextendable joints; those who are seriously affected have lax ligaments, dissecting aneurysms, dislocated eye lenses, pectus excavatum, and scoliosis. Surgical repair of aneurysms and hernias is usually successful in this population, though healing difficulties may be encountered.¹⁰³ Cutis laxa is a disease in which an elastase inhibitor deficiency gives rise to defective elastic tissue. Patients with this disease have thick, coarse, and drooping skin, along with hernias, aneurysms, heart disease, and emphysema. Unlike patients with the other heritable diseases mentioned, cutis laxa patients often show no impairment of wound healing.¹⁰⁵

Hypothermia

Hypothermia may develop as a consequence of administration of anesthetic drugs, exposure to cold, or redistribution of body heat; it leads to peripheral vasoconstriction and impaired wound oxygen delivery.¹⁰⁶ Wound tensile strength increases more slowly when healing occurs in a cold environment. Prevention or correction of hypothermia reduces the wound infection rate and increases collagen deposition in patients undergoing abdominal surgery.¹⁰⁷ Preoperative systemic and local warming also reduces the wound infection rate in patients undergoing elective operations.¹⁰⁸ A warm body temperature must be maintained in all wounded patients to reduce subcutaneous vasoconstriction and maximize wound healing potential.

Oxygen

Tissue oxygenation is necessary for aerobic metabolism, fibroblast proliferation, collagen synthesis, and the antimicrobial oxidative burst of inflammatory cells. Transcutaneous oxygen tension is directly correlated with wound healing.¹⁰⁹ Wound tissue oxygenation is determined by blood perfusion, hemoglobin dissociation, local oxygen consumption, fraction of inspired oxygen ($F_{I}O_2$), oxygen-carrying capacity (as measured by hemoglobin content), arterial oxygen tension (P_aO_2), circulating blood volume, cardiac function, arterial inflow, and venous drainage.^{106,110} Each of these variables should be addressed in promoting wound healing.

Supplemental administration of oxygen (inspired or hyperbaric) has beneficial effects on wound healing. The incidence of infection in surgical wounds can be reduced by improving the $F_{I}O_2$ with supplemental oxygen.¹¹¹ In a study of patients undergoing colon surgery, for example, the wound infection rate was 50% lower when an $F_{I}O_2$ of 0.8 was maintained intraoperatively and for 2 hours postoperatively than when an $F_{I}O_2$ of 0.3 was maintained.¹¹² Hyperbaric oxygen therapy (i.e., the delivery of oxygen in an environment of increased ambient pressure) has been used for treatment of many types of wounds in which tissue hypoxia may impair healing.⁴³ It increases tissue oxygen concentrations tenfold while also causing vasoconstriction, which results in decreased posttraumatic edema and decreased compartment pressures.¹¹³ The elevated pressure and hyperoxia induced by hyperbaric oxygen therapy may promote wound healing; for patients with an acute wound, this modality may be a useful adjunct in treating limb-threatening injury, crush injury, and compartment syndrome.⁴³

Circulating volume can be improved by administering crystalloids or blood. However, anemia alone is not associated with impaired wound healing unless it is severe enough to limit circulating blood volume.¹¹⁴ The vasculature may be compromised either systemically (e.g., by diabetes mellitus or peripheral vascular disease) or locally (e.g., by trauma or scar). Vascular bypass may be necessary to improve tissue oxygenation in patients with poor arterial inflow.⁹⁷

Tobacco Smoking

Tobacco smoking reduces tissue oxygen concentrations, impairs wound healing, and contributes to wound infection and dehiscence.^{115,116} The effects of smoking are attributable to vasoconstriction (caused by nicotine), displacement of oxygen binding (resulting from the high affinity of carbon monoxide for hemoglobin), increased platelet aggregation,¹¹⁷ impairment of the inflammatory cell oxidative burst,¹¹⁸ endothelial damage, and the development of atherosclerosis.^{115,116,119} All acutely injured patients should stop smoking, and ideally, all noninjured patients scheduled to undergo surgery should stop smoking at least 3 weeks before an elective surgical wound is made.^{118,120} Like smoked tobacco, transcutaneous nicotine patches alter the inflammatory cell oxidative burst and cause vasoconstriction; accordingly, they too should not be used when a wound is present.¹¹⁸

Malnutrition

On average, hospitalized patients show a 20% increase in energy expenditure, and this increase calls for appropriate nutritional compensation.⁹⁷ Good nutritional balance and adequate caloric intake (including sufficient amounts of protein, carbohydrates, fatty acids, vitamins, and other nutrients) are necessary for normal wound healing.¹²¹

All patients who have sustained wounds should undergo nutritional assessment,¹²² which typically includes measuring serum

levels of albumin, protein, prealbumin, transferrin, and insulinlike growth factor-1 (IGF-1).⁹⁷ The serum albumin level is one of the best predictors of operative mortality and morbidity.¹²³ A value lower than 2.5 g/dl is considered severely depressed, and a value lower than 3.4 g/dl is associated with higher perioperative mortality.^{124,125} Protein provides an essential supply of the amino acids used in collagen synthesis, and hypoproteinemia results in impaired healing; consequently, it is not surprising that protein replacement and supplementation can improve wound healing.^{126,127} In particular, supplementation specifically with the amino acids arginine, glutamine, and taurine (which are essential for anabolic processes and collagen synthesis) is known to enhance wound healing.¹²⁸⁻¹³⁰ Glutamine is the most abundant free amino acid in the body, and under catabolic conditions, it is released from muscle unless provided as a supplement.

Vitamins C, A, K, and D are essential for normal healing. Vitamin C (ascorbic acid) hydroxylates the amino acids lysine and proline during collagen synthesis and cross-linking. A deficiency of this vitamin causes scurvy, marked by failed healing of new wounds and dehiscence of old wounds. Vitamin C supplementation (100 to 1,000 g/day) can improve wound healing.^{97,130} Vitamin A (retinoic acid) is essential for normal epithelialization, proteoglycan synthesis, and normal immune function.¹³¹⁻¹³³ Retinoids and topical tretinoin may help foster acute wound healing by accelerating epithelialization of full- and partial-thickness wounds, activating fibroblasts, increasing type III collagen synthesis, and decreasing metalloprotease activation.^{134,135} Oral retinoid treatment significantly increases the decreased hydroxyproline content, tumor growth factor- β (TGF- β) level, and IGF-1 concentration associated with corticosteroids.¹³⁴ In addition, all aspects of corticosteroid-impaired healing—other than wound contraction—can be reversed by providing supplemental oral vitamin A at a recommended dosage of 25,000 IU/day.¹³⁶ The retinoic acid derivative isotretinoin (13-*cis*-retinoic acid), however, impairs wound epithelialization and delays wound healing.¹³⁷ Vitamin K is a cofactor in the synthesis of coagulation factors II, VII, IX, and X, as well as thrombin. Consequently, vitamin K is necessary for clot formation and hemostasis, the first step in acute wound healing. Vitamin D is required for normal calcium metabolism and therefore plays a necessary role in bone healing.

Dietary minerals (e.g., zinc and iron) are also essential for normal healing. Zinc is a necessary cofactor for DNA and RNA synthesis. A deficiency of this mineral can lead to inhibition cell proliferation, deficient granulation tissue formation,¹³⁸ and delayed wound healing.¹³⁹ Zinc replacement and supplementation can improve wound healing.¹³⁰ However, daily intake should not exceed 40 mg of elemental zinc, because excess zinc can immobilize macrophages, bind copper, and depress wound healing.¹⁴⁰ Iron is also a cofactor for DNA synthesis, as well as for hydroxylation of proline and lysine in collagen synthesis.⁹⁷ However, iron deficiency anemia does not appear to affect wound strength.¹⁴¹

Jaundice

The effect of jaundice on wound healing is controversial. Jaundiced patients appear to have a higher rate of postoperative wound healing complications,¹⁴² as well as a lower level of collagen synthesis.¹⁴³ However, obstructive jaundice does not affect healing of blister wounds in humans.¹⁴³ Jaundiced animals show a significant delay in collagen accumulation within the wound, but no significant reduction in the mechanical strength of the wound.¹⁴⁴ Biliary drainage may be considered in jaundiced patients with

wounds; this measure will improve collagen synthesis, though it may not have any appreciable effect on the healing rate.¹⁴³

Age

Aging has a deleterious effect on the capacity for wound healing.¹⁴⁵ Increasing age is associated with an altered inflammatory response, impaired macrophage phagocytosis, and delayed healing.¹⁴⁶ Nevertheless, even though the wound healing phases begin later in elderly persons, proceed more slowly, and often do not reach the same level that they would in younger persons, elderly patients are still able to heal most wounds with ease.¹⁴⁷

Diabetes Mellitus

Diabetes mellitus is associated with poor wound healing and an increased risk of infection. Diabetic neuropathy leads to sensory loss (typically in the extremities) and diminished ability to detect or prevent injury and wounding. Once present, wounds in diabetic patients heal slowly. The etiology of this healing impairment is multifactorial. Diabetes is associated with impaired granulocyte function and chemotaxis, depressed phagocytic function, altered humoral and cellular immunity, peripheral neuropathy, peripheral vascular disease, and various immunologic disturbances, any of which may hinder wound healing.¹⁴⁸⁻¹⁵¹ In addition, it is associated with a microangiopathy that can limit perfusion and delivery of oxygen, nutrients, and inflammatory cells to the healing wound.¹⁵² Diabetes-induced impairment of healing, as well as the attendant morbidity and mortality, may be reduced by tightly controlling blood sugar levels with insulin.¹⁵³ Diabetic patients must also closely monitor themselves for wounds and provide meticulous care for any wounds present.

Uremia

Uremia and chronic renal failure are associated with weakened host defenses, an increased risk of infection, and impaired wound healing.¹⁵⁴ Studies using uremic animal models show delayed healing of intestinal anastomoses and abdominal wounds.¹⁵⁵ Uremic serum also interferes with the proliferation of fibroblasts in culture.^{103,155} Treatment of this wound healing impairment includes dialysis.

Uremic patients with wounds may experience bleeding complications. In this situation, appropriate evaluation includes determining the prothrombin time (PT), the activated partial thromboplastin time (aPTT), the platelet count, and the hematocrit. Treatment includes dialysis without heparin; administration of desmopressin (0.3 μ g/kg), cryoprecipitate, conjugated estrogens (0.6 mg/kg/day I.V. for 5 days),¹⁵⁶ and erythropoietin; and transfusion of red blood cells to raise the hematocrit above 30%.^{157,158}

Uremic patients with hyperparathyroidism may also exhibit the uremic gangrene syndrome (calciophylaxis), which involves the spontaneous and progressive development of skin and soft tissue wounds, usually on the lower extremities. Patients with this syndrome typically are dialysis dependent and have secondary or tertiary hyperparathyroidism. Wound biopsies demonstrate fat necrosis, tissue calcification, and microarterial calcification.¹⁵⁹ Treatment includes local wound care, correction of serum phosphate levels with oral phosphate binders,¹⁶⁰ correction of calcium levels with dialysis, and subtotal parathyroidectomy.¹⁵⁹

Drugs

Steroids Corticosteroids are anti-inflammatory agents that inhibit all aspects of healing, including inflammation, macrophage migration, fibroblast proliferation, protein and collagen synthesis,

development of breaking strength, wound contraction, and epithelialization.^{103,136,161} In the setting of an acute wound that fails to heal, corticosteroid doses may be reduced, vitamin A administered topically or systemically, and anabolic steroids given to restore steroid-retarded inflammation.^{103,136}

Unlike corticosteroids, anabolic steroids accelerate normal collagen deposition and wound healing. Oxandrolone is an oral anabolic steroid and testosterone analogue that is employed clinically to treat muscle wasting, foster wound healing, and mitigate the catabolism associated with severe burn injury. Supplementation with this agent leads to significant improvements in the wound healing rate.¹⁶² In burn patients treated with oral oxandrolone, hospital length of stay is significantly reduced, and the number of necessary operative procedures is decreased.¹⁶³ In ventilator-dependent surgical patients receiving oxandrolone, however, the course of mechanical ventilation is longer than in those not treated with oxandrolone. It has been suggested that the very ability of oxandrolone to enhance wound healing may increase collagen deposition and fibrosis in the later stages of ARDS and thereby prolong recovery.¹⁶⁴ Acute elevation of liver enzyme levels has been seen in some patients treated with oxandrolone; accordingly, hepatic transaminase concentrations should be intermittently monitored in all patients treated with this agent.¹⁶³

Chemotherapeutic agents Both wound healing and tumor growth depend on metabolically active and rapidly dividing cells. Consequently, chemotherapeutic anticancer drugs that hinder tumor growth can also impair wound healing. These agents (which include adrenocorticosteroids, alkylating agents, antiestrogens, antimetabolites, antitumor antibodies, estrogen, progestogens, nitroureas, plant alkaloids, and random synthetics) attenuate the inflammatory phase of wound healing, decrease fibrin deposition,

reduce the synthesis of collagen by fibroblasts, and delay wound contraction.⁹⁷ Some cytotoxic drugs (e.g., methotrexate and doxorubicin) substantially attenuate the early phases of wound repair and reduce wound tear strength.¹⁶⁵ The magnitude of these effects is influenced by the timing of the chemotherapeutic agent's delivery in relation to the time when the wound is sustained. Preoperative delivery has a greater adverse effect on healing; for example, doxorubicin impairs wound healing to a greater extent if given before operation than if treatment is delayed until 2 weeks after operation.¹⁶⁶ Chemotherapy also results in myelosuppression and neutropenia that can decrease resistance to infection, allowing small wounds to progress to myonecrosis and necrotizing soft tissue infections.¹⁶⁷ In all acutely wounded patients who have recently been treated with, are currently taking, or will soon begin to take chemotherapeutic agents, the wounds must be closely observed for poor healing and complications.

Other drugs Many other commonly used drugs affect wound healing and thus should be avoided in the setting of an acute wound. Nicotine, cocaine, ergotamine, and epinephrine all cause vasoconstriction and tissue hypoxia. Nonsteroidal anti-inflammatory drugs (e.g., ibuprofen and ketorolac) inhibit cyclooxygenase production and reduce wound tensile strength. Colchicine decreases fibroblast proliferation and degrades newly formed extracellular matrix. Antiplatelet agents (e.g., aspirin) inhibit platelet aggregation and arachidonic acid-mediated inflammation. Heparin and warfarin impair hemostasis by virtue of their effects on fibrin formation.^{84,168,169} As noted [see *Malnutrition, above*], isotretinoin inhibits wound epithelialization and delays wound healing.¹³⁷ Vitamin E (α -tocopherol) impairs collagen formation, inflammation, and wound healing¹⁷⁰; topical application of this agent can cause contact dermatitis and worsen the cosmetic appearance of scars.⁹⁵

Discussion

Physiology of Wound Healing

Wound healing is not a single event but a continuum of processes that begin at the moment of injury and continue for months. These processes take place in much the same way throughout the various tissues of the body and, for the purposes of description, may be broadly divided into three phases: (1) inflammation, (2) migration and proliferation, and (3) maturation [see *Figure 3*]. Humans, unlike (for instance) salamanders, lack the ability to regenerate specialized structures; instead, they heal by forming a scar that lacks the complex and important skin structures seen in unwounded skin [see *Figure 4*].

INFLAMMATORY PHASE

The inflammatory phase of wound healing begins with hemostasis, followed by the arrival first of neutrophils and then of macrophages. This response is most prominent during the first 24 hours after a wound is sustained. Signs of inflammation (i.e., erythema, edema, heat, and pain) are apparent, generated primarily by changes in the venules on the distal side of the capillary bed. In clean wounds, signs of inflammation dissipate relatively quickly, and few if any inflammatory cells are seen after 5 to 7 days. In contaminated wounds, inflammation may persist for a prolonged period.

Because wounds bleed when blood vessels are injured, hemostasis is essential. In the first 5 to 10 minutes after wounding, vasoconstriction contributes to hemostasis, and the skin blanches as a result. Vasoconstriction is mediated by catecholamines (e.g., epi-

nephrine and norepinephrine) and prostaglandins (e.g., prostaglandin $F_{2\alpha}$ [$PGF_{2\alpha}$] and thromboxane A_2 [TXA_2]). As vessels contract, platelets aggregate and adhere to the blood vessel collagen exposed by the injury. Aggregating platelets release alpha-granule proteins, resulting in further platelet aggregation and triggering cytokine release. The cytokines involved in cutaneous wound healing include epidermal growth factors, fibroblast growth factors, transforming growth factor- β , platelet-derived growth factor, vascular endothelial growth factor (VEGF), tumor necrosis factor- α (TNF- α), interleukin-1 (IL-1), IGF-1, granulocyte colony-stimulating factor, and granulocyte-macrophage colony-stimulating factor.¹⁷¹ Some of these cytokines have direct effects early in the healing process; others are bound locally and play critical roles in later healing phases. The use of specific cytokines to reverse healing deficits or promote wound healing appears to be a promising clinical tool and is currently the subject of ongoing basic scientific and clinical research.¹⁷²

The coagulation cascade also contributes to hemostasis. The extrinsic pathway is essential to hemostasis and is stimulated by the release of tissue factor from injured tissue; the intrinsic cascade is not essential and is triggered by exposure to factor XII. Both coagulation pathways lead to the generation of fibrin, which acts with platelets to form a clot in the injured area [see *1:4 Bleeding and Transfusion*]. Fibrin both contributes to hemostasis and is the primary component of the provisional matrix [see *Migratory and Proliferative Phase, Provisional Matrix Formation, below*].

Figure 3 Depicted are the phases of wound healing. In the inflammatory phase (top, left), platelets adhere to collagen exposed by damage to blood vessels to form a plug. The intrinsic and extrinsic pathways of the coagulation cascade generate fibrin, which combines with platelets to form a clot in the injured area. Initial local vasoconstriction is followed by vasodilatation mediated by histamine, prostaglandins, serotonin, and kinins. Neutrophils are the predominant inflammatory cells (a polymorphonucleocyte is shown here). In the migratory and proliferative phase (top, right; bottom, left), fibrin and fibronectin are the primary components of the provisional extracellular matrix. Macrophages, fibroblasts, and other mesenchymal cells migrate into the wound area. Gradually, macrophages replace neutrophils as the predominant inflammatory cells. Angiogenic factors induce the development of new blood vessels as capillaries. Epithelial cells advance across the wound bed. Wound tensile strength increases as collagen produced by fibroblasts replaces fibrin. Myofibroblasts induce wound contraction. In the maturational phase (bottom, right), scar remodeling occurs. The overall level of collagen in the wound plateaus; old collagen is broken down as new collagen is produced. The number of cross-links between collagen molecules increases, and the new collagen fibers are aligned so as to yield an increase in wound tensile strength.

Vasoconstriction and hemostasis are followed by vasodilatation, which is associated with the characteristic signs of erythema, edema, heat, and pain. Vasodilatation is mediated by prostaglandins (e.g., PGE_2 and PGI_2 [prostacyclin]), histamine, serotonin, and kinins.^{173,174} As the blood vessels dilate, the endothelial cells separate from one another, thereby increasing vascular permeability. Inflammatory cells initially roll along the endothelial cell lining, subsequently undergo integrin-mediated adhesion, and finally trans-migrate into the extravascular space.¹⁷⁵

For the first 48 to 72 hours after wounding, neutrophils are the predominant inflammatory cells in the wound. About 48 to 96 hours after wounding, however, monocytes migrate from nearby tissue and blood and transform into macrophages, and eventually, macrophages become the predominant inflammatory cells in the wound. Both neutrophils and macrophages engulf damaged

tissue and bacteria and digest them. After neutrophils phagocytose damaged material, they cease to function and often release lysosomal contents, which can contribute to tissue damage and a prolonged inflammatory response. Macrophages, however, are essential to wound healing and do not cease to function after phagocytosing bacteria or damaged material.¹⁷⁶ In the wound environment, macrophages also secrete collagenase, elastase, and matrix metalloproteinases (MMPs) that break down damaged tissue. Macrophages also produce cytokines that mediate wound-healing processes, as well as IL-1 (which can lead to a systemic response, including fever) and $\text{TNF-}\alpha$.¹⁷¹

MIGRATORY AND PROLIFERATIVE PHASE

The migratory and proliferative phase is marked by the attraction of epidermal cells, fibroblasts, and endothelial cells to the

Figure 4 Shown are the key anatomic components of the skin.

wound. Cells migrate along the scaffolding of fibrin and fibronectin. This process involves the upregulation of integrin receptor sites on the cell membranes, which allows the cells to bind at different sites in the matrix and pull themselves through the scaffolding. Migration through the provisional matrix is facilitated by proteolytic enzymes. Cytokines and growth factors then stimulate the proliferation of these cells.^{171,176}

Epithelialization

Within approximately 24 hours of injury, epidermal cells from the wound margin and skin appendages begin to migrate into the wound bed. These migrating epidermal cells dissect the wound, separating desiccated eschar from viable tissue.⁸⁰ At 24 to 48 hours after wounding, epidermal cells at the wound margin begin to proliferate, producing more migrating cells.¹⁷¹ As epidermal migration is initiated, the desmosomes that link epidermal cells together and the hemidesmosomes that link the epidermal cells to the basement membrane disappear.¹⁷⁷ Migrating epidermal cells express integrin receptors that allow interaction with extracellular matrix proteins, laminin, collagen, and fibrin clot.¹⁷⁸ When epidermal cells migrating from two areas meet, contact inhibition prevents further migration. The cells making up the epidermal monolayer then differentiate, divide, and form a multilayer epidermis.

Provisional Matrix Formation

Formation of the provisional matrix and granulation tissue begins approximately 3 to 4 days after wounding. Fibroblasts synthesize an extracellular matrix of fibrin, fibronectin, and proteoglycans that supports epidermal and endothelial cell migration and proliferation.^{178,179} Proteoglycans (e.g., dermatan sulfate, heparin, heparan sulfate, keratan sulfate, and hyaluronic acid) consist of a protein core that is linked to one or more glycosaminoglycans; they anchor proteins and facilitate the alignment of collagen into fibrils.

Fibrin becomes coated with vitronectin and fibronectin, which are glycoproteins that facilitate the adhesion of migrating fibro-

blasts and other cells to the provisional extracellular matrix.¹⁸⁰ By influencing cellular attachment, fibronectin helps modulate cell migration into the wound.¹⁸¹ In addition, the fibrin-fibronectin lattice binds various cytokines that are released at the time of injury and serves as a reservoir for these factors in the later stages of healing.¹⁸²

Fibroblasts then replace the provisional extracellular matrix with a collagen matrix, and the wound gains strength. The rate of collagen synthesis increases greatly after the initial 3 to 5 days and continues at an increased rate for 21 days before gradually declining.¹⁸³ Of the many types of collagen, the ones that are of primary importance in the skin are types I and III. Approximately 80% to 90% of the collagen in the skin is type I collagen; the remaining 10% to 20% is type III. The percentage of type III collagen is higher in embryonic skin and in skin that is in the early stages of wound healing.

Collagen molecules are synthesized by fibroblasts. Lysine and proline residues within the collagen molecule become hydroxylated after being incorporated into polypeptide chains. This process requires specific enzymes, as well as various cofactors (i.e., oxygen, vitamin C, α -ketoglutarate, and ferrous iron). The result is procollagen, which is released into the extracellular space. Individual collagen molecules then align and associate with one another to form fibrils. Covalent cross-links form between various combinations of the hydroxylated residues (lysine and hydroxylysine) in aligned collagen fibrils, with the strongest links occurring between hydroxylysine and hydroxylysine. These cross-links are essential to the tensile strength of the wound. Cofactor deficiencies (e.g., vitamin C deficiency in scurvy) and the use of corticosteroids can lead to the synthesis of weak, underhydroxylated collagen that is incapable of generating strong cross-links.

Angiogenesis

The growth of new blood vessels, which is necessary to support the wound tissue, begins 2 to 3 days after wounding. This process of angiogenesis may be stimulated by the hypoxic and acidic

wound microenvironment, as well as by cytokines (e.g., VEGF) derived from epidermal cells and macrophages.^{171,184} Endothelial cells from surrounding vessels express fibronectin receptors and grow into the provisional matrix. These migrating endothelial cells create paths in the matrix for developing capillaries by releasing plasminogen activator, procollagenase, heparanase, and MMPs, which break down fibrin and basement membranes.^{171,185} The budding capillaries join and initiate blood flow. As the wounded area becomes better vascularized, the capillaries consolidate to form larger blood vessels or undergo apoptosis.¹⁸⁶

MATURATIONAL PHASE

Wound Contraction

Myofibroblasts are specialized fibroblasts containing alpha-smooth muscle actin microfilaments that contribute to wound contraction.^{187,188} The wound edges are pulled together by the contractile forces supplied by the myofibroblast. Wound contraction generally begins in the 4- to 5-day period after wounding and continues for 12 to 15 days or until the wound edges meet. The rate at which contraction occurs varies with the laxity of the tissue and is

highest at anatomic sites with redundant tissue. Excessive contraction can lead to contracture, a pathologic scarring that impairs the function and appearance of the scar.

Scar Remodeling

Collagen remodeling begins approximately 3 weeks after wounding. Collagen synthesis is downregulated, the rates at which collagen is synthesized and broken down reach equilibrium, and the wound becomes less cellular as apoptosis occurs. During this process, the extracellular matrix, including collagen, is continually remodeled and synthesized in a more organized fashion along stress lines.¹⁸³ Collagen breakdown is mediated by MMPs.¹⁸⁹ The number of cross-links between collagen fibers increases,¹⁸³ and the realigned, highly cross-linked collagen is much stronger than the collagen produced during the earlier phases of healing. The tensile strength of the wound increases rapidly for 6 weeks after injury; accordingly, during this period, heavy lifting and any other activity that applies stress across the wound should be avoided. After the initial 6 weeks, tensile strength increases more slowly for a further 6 to 12 months, though it never reaches the tensile strength of unwounded tissue [see Figure 2].

8 PREPARATION OF THE OPERATING ROOM

T. Forcht Dagi, MD, MPH, FACS, FCCM, and William Schecter, MD, FACS, FCCM

This chapter concentrates on the general principles of operating room (OR) design and operation. The OR is designed to permit sterile, safe, painless, and effective surgical intervention to improve the lives of patients. Advances in science and technology have significantly increased the complexity of the OR environment. With further advances, the OR will continue to evolve.

The basic aspects of OR design have not changed since the late 19th century, except for changes necessitated by the introduction of complex surgical imaging and monitoring equipment. Effective integration of this equipment into the confined OR space is essential. This chapter focuses on general principles of planning and operation rather than the specific requirements of individual surgical specialties.

Efficient operation of the OR depends on many individuals, some seldom seen, whose skills are essential. They are rarely acknowledged and easily overlooked. Continuous, respectful communication is essential for safe and successful outcomes.

General Principles of OR Design and Construction

PHYSICAL LAYOUT

The basic physical design of the OR is determined first by requirements for patient positioning, illumination, anesthesia, and instrumentation and second by considerations of storage, patient and staff movement, and communication. Basic OR design has not changed substantially over the past century. More recently, however, advances in minimally invasive surgery, intraoperative imaging, patient monitoring, surgical navigation, surgical robotics, and data connectivity have stimulated surgeons and architects to rethink the layout of the OR.

Positioning the Patient

The anesthesia machine is positioned at the head of the table so that the anesthesiologist has an unimpeded view of the machine, monitors, airway, and intravenous (IV) fluids. The suction tubing and electrocautery cords are usually brought off the field toward the feet. However, they may be brought off the side or head of the patient in selected cases depending on equipment location and room orientation.

Laparotomy

The patient is positioned supine on the operating table. The arms may be tucked in at the patient's sides or placed on well-padded arm boards at 90° angles to the table. Care must be taken to avoid hyperextending the arms to avoid injury to the brachial plexus. If the arms are tucked in at the side, the

area of the cubital tunnel must be well padded to avoid injury to the ulnar nerve. The surgeon generally stands on the patient's right and the assistant on the left. For pelvic procedures, the right-handed surgeon may elect to stand on the patient's left. The scrub nurse stands next to the instrument tray placed on a Mayo stand over the patient's legs. The back table containing additional instruments is placed at the foot of the bed (Figure 1A).

Two sets of ceiling lights are positioned over the field. In many cases, a head light worn by the surgeon provides additional focused illumination. For pelvic procedures, access to the perineum is either helpful or essential. The patient should be placed in the Lloyd-Davies position. The patient's legs are placed in well-padded leg holders attached to the side of the OR table. The distal portion of the table is lowered to form a right angle with the proximal table. The patient is moved distally so that the sacrum is positioned adjacent to the table brake. Care is taken to protect the airway, arms, and legs during repositioning. A foam pad is placed between the sacrum and the OR table. The leg holders are positioned to avoid abduction of the hips. Care is taken to ensure padding in the area of the peroneal nerves, feet, and calves. Peroneal nerve palsy and compartment syndrome attributable to prolonged pressure are risks. Morbid obesity is a relative contraindication to the Lloyd-Davies position because of the risk of a traction injury to the sciatic nerve.

Thoracotomy

The patient is placed in the full lateral position. A bean bag is a useful device to hold the patient in position. It holds its shape when a suction device is applied. An axillary roll, either a rolled sheet or an IV bag, is placed to protect the brachial plexus. Alternatively, a large pillow may be placed under the axilla and chest. Pillows are useful for supporting the legs. The bottom leg should be slightly flexed and the top leg extended. The position should be secured by the application of 2-inch tape to the area of the iliac crest. Care must be taken to protect the skin from the tape to avoid blister formation. The arms are extended in front of the patient. They may rest on an arm board protected by pillows or sheets. Alternatively, the top arm may be supported by a well-placed "airplane splint." As in laparotomy, the surgeon and assistant stand on either side of the patient and the scrub nurse stands toward the feet. Two lights are positioned over the patient. The use of a head light by the operating surgeon is routine in many situations (Figure 1B).

Thyroidectomy and Parathyroidectomy

Thyroidectomy and parathyroidectomy are the most common neck procedures performed by general surgeons.

a

b

c

Figure 1 Patient positioning: (a) laparotomy, (b) thoracotomy, and (c) thyroidectomy.

Preoperative evaluation should include assessment of cervical spine mobility. The patient is positioned supine on the OR table. After endotracheal intubation, a sheet roll is placed posterior to the scapula. The head is extended and placed on a foam "donut" pad, avoiding excess tension on the cervical spine. Extension of the head should be avoided in the presence of limited cervical spine mobility. The head of the table is elevated to reduce venous pressure. Two ceiling lights are positioned over the neck. Most surgeons use a head light to provide additional focused illumination. The scrub nurse stands next to the Mayo stand holding the instrument tray over the patient's feet (Figure 1C).

A similar position is employed for neck explorations. For unilateral neck exploration, the patient's head is turned away from the side of the planned incision.

DESIGN STANDARDS

Standards for new construction and major remodeling of ORs in the United States generally fall under the jurisdiction of state and local agencies. These agencies, in turn, often incorporate guidelines published by the Department of Health and Human Services,¹ as well as other groups and agencies,

such as the Occupational Safety and Health Administration (OSHA) and the Nuclear Regulatory Commission.²⁻⁵

Numerous articles and books discuss the various aspects of OR design.⁶⁻¹⁰ The American Institute of Architects has published a comprehensive set of guidelines for health care facility design that includes a detailed discussion of OR design.¹¹ Along with such guidelines and recommendations obtained from specialty surgical, anesthesiology, biomedical engineering and nursing associations, the design of new ORs must consider local needs and perspectives. The design of a new OR should be a collaborative effort reflecting the efforts of clinical services, support services, and administration.

DESIGN PROCESS AND CONSIDERATIONS

Designs must accommodate work flow and patient movement. Important considerations include the mix of inpatient and outpatient surgery, the design of the hospital or institution (including proximity to clinical services such as radiology and pathology), the surgical specialties to be served, accessibility to perioperative care units, accessibility of supplies, and removal of waste materials. The need for intraoperative fluoroscopy and sectional imaging, shielding, ceiling-mounted

microscopes, and surgical robotics and similar advanced technologies will be influential. It is important to allow for flexibility and to anticipate the introduction of new technologies over the life of the design. Time motion studies, simulations, and models may prove helpful and contribute to OR efficiency long term. Balancing flexibility and cost is a continuing challenge.¹²

The geography and physical relationship of clean and less clean areas in the operating suite determine many other aspects of the OR suite. There are two designs in common use. The first involves one or more clean hubs. The ORs are situated centrifugally in spokelike fashion. Clean and sterile equipment and supplies that must be on hand for immediate use are stored in the hub. A peripheral corridor typically affords access to perioperative care units, instrument and anesthesia workrooms, clean storage, staff lounges, and other facilities. Entry and egress from the suite and access to the OR front desk and reception area also involve the peripheral corridor. In the simplest embodiment, four ORs surround a hub. The number can be greater or smaller. Controlled movement through the hub or hubs drives this design.

The second model uses corridors rather than hubs and spokes. Supply rooms are typically situated between adjacent rooms. A less common variation builds a separate supply room next to each individual OR. Older ORs were designed with one door only. Current design favors two, one connecting to the more sterile area and the other to the less sterile area.

The OR must balance the restrictions on access needed for safety and efficiency with freedom of movement for personnel and patients. This balance is equally important in emergency situations and during complex and lengthy operations.

Should ORs be dedicated to specific surgical specialties? There are practical and logistical advantages to dedicated rooms, especially in cardiac surgery, neurosurgery, trauma, and ophthalmology. However, specialty-specific rooms can limit scheduling flexibility. Although it is hard to imagine justifying a room so narrowly designed that it absolutely cannot be used for more than one specialty, dedicated rooms might be emphasized in one institution and versatility in another. Each approach has its advocates. Design and equipment should ultimately reflect expected and projected case mix.

Finally, the design of the OR suite must facilitate cleaning, disinfection and efficient turnover, and the installation and maintenance of installed equipment.

STORAGE

The OR design must provide adequate storage space for urgently required supplies. Storage in hallways and inside the OR can create obstructions and hazards.

CRITICAL DEVICES AND EMERGENCY EQUIPMENT

Critical devices, as well as emergency supplies and instruments, must be prepared and positioned for immediate deployment. Accessories should be stored next to the instruments that need them.

Some hospitals have mass casualty response as part of their mission. These institutions will have special requirements for versatility, equipment, storage, and supplies. The specific design requirements for response to mass casualty events,

including nuclear, biological, chemical, and radiation incidents, are not addressed in this chapter.

PHYSICAL REQUIREMENTS

The fundamental model for OR design is a quadrangular room with minimum dimensions of 20 × 20 ft or 7 × 7 m. More often, the dimensions are closer to 30 × 30 ft or 10 × 10 m, so as to accommodate more specialized cardiac, neurosurgical, minimally invasive, orthopedic, and multiteam procedures. Smaller rooms are generally adequate for minor surgery and for procedures such as cystoscopy and eye surgery.

Ceiling height should be at least 10 ft or 3.5 m to allow ceiling mounting of operating lights, microscopes, robots, navigational systems, and other equipment. An additional 1 to 2 ft or 0.5 to 0.75 m of ceiling height may be advisable if x-ray or other boom equipment is to be permanently mounted. In ORs designed to accept intraoperative sectional imaging devices (computed tomography [CT] and magnetic resonance imaging [MRI]), the floors may be elevated to accommodate cabling and wiring for power and data connections. When floors are elevated, the overall height of the OR has to be increased.

Some institutions design or redesign the entire OR suite with the potential to accommodate oversized equipment as well as conduits and cables in both the ceiling and floor. Others prefer to customize individual rooms.

OR and perioperative facilities may be specially constructed to withstand environmental hazards such as earthquakes, tornadoes, and floods or hardened to contend with hostile military or terrorist attack. Standards and specifications for this type of construction fall outside the scope of this chapter.

COMPUTERIZATION, COMMUNICATION, AND DATA EXCHANGE: VOICE, VIDEO, AND DATA

Computers, telephones, imaging, and other systems for data capture, analysis, and exchange should be integrated into the OR design. The ubiquitous deployment of radiology Picture Archiving and Communication Systems (PACS) and the potential of digital pathology to improve surgical pathology services mandate the installation of high-speed broadband connections. Two-way audio with teleconferencing capabilities enables teleconsultation and teaching from and in the OR.

Effective communication systems capable of connecting the OR team, the OR front desk, and the rest of the hospital must be accessible. Emergency communication channels must be tested at regular intervals. Most importantly, systems for communication, data exchange, and data storage retrieval must be available, preferably off-site. Off-site data storage backup is essential for hospitals likely to respond to mass casualty events or subject to environmental hazards.

ASSIMILATING NEW TECHNOLOGIES

Advances in the medical device and information technology (IT) sectors stimulate a constant stream of innovation. Nevertheless, the undisciplined introduction of new technologies can be distracting, contraproductive, and expensive. ORs should be focused on measurable benefit and integration rather than novelty. The introduction of new technologies should reduce complexity and tangibly increase therapeutic

benefits and options for patients in ways that have been recognized for more than a decade.¹³

The OR of the future will be characterized by increasing dependence on technology. Although it is essential to track new technologies, they should be assessed and introduced in a disciplined manner. Technology acquisition should be strategic. A full discussion of technology assessment in surgery is outside the purview of this chapter, but the central principles are straightforward. First, the magnitude of unmet needs should be detailed and quantified. Second, the cost-effectiveness of a new technology should be assessed. Next, competitive solutions, including substitutes for the candidate technology acquisition, should be considered. Last, the marginal benefits and burdens of new technology introduction should be quantified.

Patient Safety, OR Efficiency, and Quality Improvement

The OR is a high-stress environment with inherent risk in which members of multiple disciplines temporarily congregate to treat surgical patients. The potential for error and inefficiency is great. Conversion of this group of individuals from disciplines with differing professional cultures and skill sets into a smoothly functioning surgical team is the key to increasing patient safety and efficiency.¹⁴ Surgical team training is an effective method to achieve a “team culture” resulting in improved communication and decreased risk of error.¹⁵ The use of perioperative care protocols reduces failures of communication.¹⁶

The Joint Commission Universal Protocol became effective on July 1, 2004. The key principles of the Universal Protocol are (1) the preoperative verification process, (2) marking the correct surgical site, (3) taking a “time-out” prior to surgery, and (4) adapting the requirements to non-OR settings. The elements of the time-out concept are evolving and may include introduction of team members; patient identification; review of the patient’s history, risk factors, medications, and allergies; availability of appropriate images and equipment; goals of surgery; and potential intra- and postoperative problems. The role of a discussion of planned postoperative care at the completion of the surgical procedure prior to the emergence from anesthesia is not clear at the present time.¹⁷

The use of a protocol during the hand-over of surgical patients to intensive care results in improved care.¹⁸ Extending the team concept to postanesthesia care has resulted in improved quality of care as measured by intubation times and hospital stay following cardiac surgery.¹⁹ The use of specialty teams during surgery to improve communication and efficiency is logical, but at present, there is a paucity of studies documenting its efficacy. Continuous monitoring is essential to maintain quality.²⁰

Patient safety²¹ begins with protection of patients from misidentification, physical and chemical hazards, medication error, operative error, and improper positioning.²² The surgeon is responsible for positioning the patient and preventing positioning injury.²³ The OR team is responsible for procuring and maintaining the equipment for proper positioning and monitoring the patient intraoperatively. The entire team is responsible for preventing falls.²⁴

The risks associated with malpositioning deserve further comment. Any bony prominence is subject to injury from excessive pressure. The fragile skin of infants and older patients may be injured by dragging rather than lifting into position. The American Society of Anesthesiologists (ASA) practice advisory on the prevention of perioperative peripheral neuropathies recommends that when practical, patients should be placed in the intended position before induction of anesthesia to test for comfort.²⁵ Uncomfortable positions should be modified. This is especially important with older patients or patients with degenerative spine and joint disease or skeletal instability.

Two major preventable consequences of malpositioning are neuropathy or plexopathy and skin burns or ulceration. Approximately 80% of surgical procedures are performed with patients in the supine position. Ulnar neuropathy and brachial plexopathy are the two most common complications in this position and constitute 28% and 20% of claims, respectively, in recent closed claims studies.^{26–31} Padding of the precondylar groove of the humerus and tucking of the arms or, at the least, restriction of abduction to less than 90° help prevent this problem.²⁵

The lithotomy position is used in approximately 9% of cases and is the next most commonly used position.^{27,29} Damage to the obturator, sciatic, lateral femoral cutaneous, and peroneal nerves has been observed. These injuries account for 5% of claims for nerve damage in the Closed Claims Data Base. They represent a small but not insignificant risk.²⁶ Other patient positions have also been associated with malpositioning injuries.

OCCUPATIONAL INJURY TO THE HEALTH CARE TEAM

Professionals engaged in perioperative and surgical care are exposed to biologic, ergonomic, chemical, physical, and psychosocial occupational risks.

Biologic Risks

These risks include (1) parenteral and mucocutaneous exposure to pathogens, (2) respiratory tract exposure to pathogens, (3) exposure to the biologic components of surgical smoke, and (4) exposure to allergens in latex gloves.³² Strategies to reduce mucocutaneous exposure to pathogens include double-gloving, blunt suture needles, a neutral zone for passage of sharps, and engineered sharps injury prevention devices.³³ The use of N-95 respirator masks reduces the risk of occupational exposure to aerosolized *Mycobacterium tuberculosis* and particulate matter greater than 1 micron in size.³⁴ Health care workers with allergies to latex should avoid contact with latex gloves and tubing.

Ergonomic Risks

Health problems related to ergonomics, especially back pain, are common. These problems are associated with awkward posture at the operating table, standing for long periods of time, and back injury incurred by lifting patients.

The OR table, monitors, imaging screens, and equipment should be positioned so that the OR team’s posture and position are as comfortable as possible within the limits of patient safety. Lifting injury can be minimized by using proper patient transfer techniques and obtaining additional assistance when moving patients in the OR. Repetitive motion injury is a less common but not insignificant risk.³²

Chemical Risks

Health care workers are exposed to numerous potentially hazardous chemicals in the OR, including anesthetic gases, disinfecting and sterilizing chemicals, specimen preservatives, and chemotherapeutic drugs.³² Scavenger systems are deployed broadly and have significantly reduced exposure to anesthetic gases.³⁵ Protective gowns and gloves prevent exposure to other chemicals in the OR.

Physical Risks

Physical risks to patients and the OR team include fire, electrocution, radiation exposure, and laser energy exposure.³²

Fire The first principle of fire prevention is control of the three elements of the fire triangle: oxygen, fuel, and an ignition source.³⁶ Air/oxygen mixtures should be adjusted to reduce the fraction of inspired oxygen (FiO_2) to the lowest level consistent with patient safety and satisfactory hemoglobin oxygen saturation.³⁶ Light, heat, and electrical sources of ignition should be carefully monitored and kept away from paper drapes. The use of alcohol-based skin preparation solutions should be minimized if possible.³⁷ The use of the electrocautery or laser energy in the airway or in the unprepared intestinal lumen in the presence of high concentrations of oxygen increases the risk of fire.

Radiation exposure Exposure to ionizing radiation is inherently dangerous. For this reason, the extent of exposure must be minimized through the use of all protective means available. Although the hazards of radiation were witnessed early in the 20th century, how exposure was to be calculated and what acute and cumulative doses were dangerous could not be determined until later. In 1928, the International Commission on Radiological Protection (ICRP) was formed to study and set standards for radiation protection. The National Council on Radiation Protection (NCRP) was established in the United States to help set US policy on radiation protection.³⁷ Until recently, guidelines for radiation exposure have been based on annual exposure limits (maximal permissible yearly dose). The historical means of dosimetry underestimated exposure because of technical limitations and sampling error. For this reason, guidelines now focus on lifetime accumulated exposure as a more useful surrogate for the real risks in those with chronic or prolonged exposure.

Concessions to higher annual dose limits were made for workers allowed higher radiation exposure because of occupational responsibilities. These were called “classified” workers, and they were subjected to strict monitoring and regular examination. Radiologists have been considered classified workers, but not surgeons. Classified workers were permitted more than three times the annual dose than nonclassified.³⁸

Empirical data suggest that the typical spinal surgeon performing fluoroscopically guided procedures may receive as much as 1.3-fold the annual whole-body radiation dose allowable for radiologists, although the level of thyroid exposure is less than 10% of the applicable limit specified by the NCRP.³⁹ A study of endovascular surgeons, in contrast, showed that their radiation exposure fell well within these limits, as well as the limits established by the ICRP.⁴⁰

Another study considered risks to the fetus of the pregnant surgeon. This risk is of particular importance early in gestation, before the pregnancy is recognized. In this study, the calculated accumulative dose received intraoperatively exceeded the threshold dose for the induction of radiation injury by at least two orders of magnitude. Approximately 2100 hours of fluoroscopy are required to reach this threshold.

Childhood cancer is another documented risk of low-dose fetal radiation exposure. The extent of this risk remains controversial. Nevertheless, the ICRP has recommended a maximum dose of 2 mSv and preferably less than 1 mSv during the declared pregnancy. With the protection afforded by a 0.5 mm lead-equivalent apron, however, the calculated expected cumulative fetal dose is less than 0.37 mSv, a figure that extrapolates to a significantly lower dose, and consequently a lower risk, than that derived from natural background radiation.

Surgeons exposed to intraoperative ionizing radiation may avail themselves of several protective strategies. A 1 mm lead-equivalent whole-body shield or apron provides 99% protection. A 0.5 mm lead-equivalent free-standing shield reduces exposure by 90%. A neck (thyroid) shield with 0.25 mm lead equivalence reduces exposure by 60%. Radiation-protective gloves reduce dosage to the hand by up to 40%.^{37,41}

Maintaining distance is also protective. Radiation attenuates with the square of the distance. For any given distance from the source of radiation, if the intensity of the radiation at a distance of $d = 1$, the intensity at any other distance is equal to $1/d^2$. Intensity diminishes as a function of the square of distance.

The effects of distance are manifested quickly. Staff exposure at 1 m distance from a C arm is 1/1000th that of the patient, even without shielding. In a model of femoral fracture, moving from the treated hip side of a patient to the contralateral side reduces exposure by a factor of 57 for the surgeon, 13 for the nurse, and 21 for the anesthetist. If the surgeon remains ipsilateral to the operative site but moves as little as 0.5 m away (cephalad) from the beam, the dose is reduced by a factor of 13, and at 1.5 m away, by a factor of 26. At 2 m from the source of radiation, the scattered radiation received by staff is very small.⁴² Nevertheless, because of the problem of accumulated lifetime exposure, no degree of exposure is ever deemed truly innocuous.

Image-guided surgery now plays a major role in many surgical disciplines, including orthopedics, vascular surgery, and urology. The cumulative radiation exposure associated with image guidance may be hazardous. The use of radionuclides for identification of sentinel nodes and intraoperative brachytherapy for the treatment of certain malignancies also creates the potential for radiation exposure.⁴³

Exposure to radiation comes from background radioactivity and from radiation sources in the workplace. The ICRP has established recommended yearly limits of radiation exposure for these two categories [see Table 1].⁴⁴ Recent studies of OR staff indicate that radiation exposure during surgical procedures employing radiation imaging techniques are well within the ICRP limits.^{45–47}

All OR personnel should wear radiation safety badges to allow monitoring of radiation exposure on a monthly basis.

Table 1 ICRP-Recommended Radiation Dose Limits⁴⁴

	Dose Limit	
	Occupational	Public
Effective dose	20 mSv/yr averaged over defined periods of 5 yr	1 mSv/yr
Annual equivalent dose in		
Lens of the eye	150 mSv	15 mSv
Skin	500 mSv	50 mSv
Hands and feet	500 mSv	—

ICRP = International Commission on Radiological Protection; mSv = millisievert.

OR personnel should wear protective lead aprons (0.25–0.5 mm in thickness) with thyroid shields during procedures in which fluoroscopy is used. Personnel frequently exposed to radiation should wear lead-containing lenses for eye protection. A mobile shield is useful for additional protection during cine runs.

OR personnel should stand as far away from the x-ray beam as possible to limit exposure. Even a distance of several feet can significantly reduce exposure. Equipment emitting ionizing radiation should be maintained and monitored to ensure proper function.⁴⁸ The use of pulsed fluoroscopy and effective collimation of images will help minimize the dose of radiation. Excessive and unnecessary imaging should be eliminated.

Laser exposure Surgical lasers are class 4 lasers that have the potential to irreparably damage the eye and burn the skin. A class 4 laser beam is 1 billion times brighter than a 100 W light bulb.⁴⁹ All OR personnel must wear protective glasses with lenses designed specifically for the wavelength of the specific laser being used. Glasses should be inspected prior to use to ensure that there are no scratches on the lens that could render the wearer vulnerable to an eye injury. The windows of the room should be shielded to protect individuals passing by. The number of personnel in a laser therapy room should be kept to a minimum.

Noise and light exposure General environmental hazards include high levels of noise and intense levels of light.^{50–52} These hazards are of equal significance to patients and to staff. One early study has indicated that elevated noise levels during orthopedic procedures (above the recommended limits of 110 dBA) were associated with significant hearing loss in orthopedic surgeons.⁵¹ Noise, excessive chatter, and even music can also pose a hazard to the patient by distracting the attention of OR personnel.

Psychosocial risks Perhaps the most underappreciated risks to the perioperative professional are psychosocial. Long hours and nighttime emergencies lead to fatigue. The high level of responsibility, the consequences of error, and the level of oversight have led to high levels of stress and burn-out.⁵³ Unfortunately, violence in the health care workplace, both verbal and physical, is common.⁵⁴ Stress reduction can be achieved by team training.¹⁵ Hospitals should have zero tolerance for workplace violence.⁵⁵

OR Design

Advances in videoendoscopic surgery and endoluminal vascular surgery since 1990 have led to the introduction of many complex electronic devices into an OR environment designed at the end of the 19th century. The promise of widespread robotics use in the future may further complicate equipment and use of space within the OR. At the same time, the importance of IT in both the performance of surgery and its documentation will only increase. These changes will inevitably require design adaptations in the OR to ensure adequate power and communication infrastructure support.⁵⁶

The ideal OR of the future will have videoendoscopic monitors, light sources, and CO₂ insufflators mounted on booms that can be introduced or withdrawn from patient care without moving heavy carts or reconnecting cables and power sources. ORs with ceiling- or floor-mounted fluoroscopy permit efficient use of catheter-based endoluminal and intravascular techniques during surgical care. Boom-mounted equipment can be easily moved, permitting more rapid room turnover between cases.

Designing rooms with the flexibility for multidisciplinary use may be more cost effective for many hospitals. In the long run, however, team training for subspecialty fields employing complex imaging equipment and catheter-based therapy may prove to be a more important factor for patient safety and efficiency than any particular OR design.⁵⁷ This is a key element in program development. Hospital administration must also commit the capital necessary to complete such a project before proceeding with program development. Balancing OR efficiency, new technology, and cost is a continuous challenge.

Environmental Issues in the OR

TEMPERATURE AND HUMIDITY

In Europe and North America, the OR is typically maintained at 18° to 26°C (64.4° to 78.8°F). A higher temperature is necessary during operations on infants and burn patients to conserve body heat. Fully gowned surgeons prefer the lower temperature of 18°C (64.4°F), but anesthesiologists prefer 21.5°C (70.7°F).⁵⁸ The optimum ambient temperature in the OR reflects a compromise between the comfort of gowned and ungowned staff. The ubiquitous deployment of patient warming devices has all but eliminated the problem of hypothermia in the adult during elective surgery.

Recent publications have indicated neurologic benefits from controlled hypothermia in the region of 34°C (93.2°F) in certain cases of asystole, cardiopulmonary arrest, and resuscitation.^{59–61} The equipment required for therapeutic hypothermia can be cumbersome.

Humidity in the OR is generally maintained between 50 and 60%. Humidity greater than 60% may cause condensation on cool surfaces. Humidity less than 50% may not suppress static electricity. Static electricity can adversely affect the function of modern computers and smart medical devices.

LIGHTING

ORs are no longer provided with skylights and northern exposure to maximize the benefit of natural illumination.

Nevertheless, effective lighting remains an important factor in reducing stress by providing clear views of the operative field, the anesthesia and monitoring systems, and the nursing area.

The standards for OR illumination were outlined by Dr. William Beck and the Illuminating Engineering Society.^{62,63} A general illumination brightness of up to 200 footcandles (ft-c) is desirable in new construction. The lighting sources should be free of glare and nonreflective.⁶⁴

The amount of light required during an operation varies with the surgeon and the operative site. Quantities of light can be measured as a function of the amount beamed on a subject (incident light) or the amount reflected (reflected light). In one study, general surgeons operating on the common bile duct found 300 ft-c sufficient because the reflectance of this tissue area is 15%. The corresponding incident light level would be 2,000 ft-c.²¹ Surgeons performing coronary bypass operations require an incident level of 3,500 ft-c.²¹ Whether changes in the color of light can improve discrimination of different tissues is unknown.

The powerful lights installed for surgery generate heat through the projection of infrared energy. This is an inefficient but inevitable byproduct of most forms of light appropriate for the OR. Much of the infrared energy can be eliminated by filtration or by heat-diverting dichroic reflectors.

There are several types of overhead lighting designs. For small ORs, a single large overhead light with one or two small satellites may suffice. Larger ORs may benefit more from several large lights with broader orbits. The larger the OR, the more important the installation of multiple light sources that can concentrate light in different areas of the operating field. This consideration is of particular importance where large body areas are exposed or where multiple sites are accessed simultaneously.

The illumination provided by overhead lighting can be usefully amplified and improved with headlights. Headlights have substituted for mobile lights in many OR suites, but both have their place. When headlights are used, spare bulbs must be kept on hand and cabling examined for damage and properly stored after each use.

During microsurgical and laparoscopic procedures, the surgical field is illuminated primarily by dint of the instruments used for visualization. The importance of ambient lighting for the remainder of the OR must not be forgotten.

All ORs should be equipped with battery-powered backup illumination and flashlights for emergency use.

OR EQUIPMENT

The modern OR is replete with medical devices designed to facilitate the work of the surgical team and to support, position, and protect the patient [see Table 2]. The equipment in the OR must be chosen and maintained with three concerns in mind: patient safety, surgical efficiency, and reduction of occupational hazards.

ELECTROSURGICAL DEVICES

The common electrosurgical device is a 500 W radiofrequency generator used to cut and coagulate tissue. A current passes from the cutting or coagulating surgical instrument to a dispersion electrode. Heat is generated at the tissue

interface as a function of resistance to the flow of current. The vaporization of intracellular water content leads to disintegration of the cell. Heat leads to the coagulation of proteins and hemostasis. Cellular debris is aerosolized. The smoke that is generated is comparable to that accompanying laser use. The smoke and its particulate content may be carcinogenic, allergenic, inflammatory, and infectious. There is little difference between laser plume and electrosurgical smoke.⁶⁵

The electrosurgical instrument requires close supervision.⁶⁶ It is very easy to become complacent in its use. The unit generates an electrical arc. In the past, these have been associated with explosions. This risk has been lessened because explosive anesthetic agents are no longer used. Nevertheless, explosion of hydrogen and methane gases in the large bowel remains a threat, especially when surgery must be performed on an unprepared bowel.⁶⁷ Because the unit and its arc generate a broad and unfiltered band of radiofrequencies, electrosurgical units may interfere with monitoring devices, most notably the electrocardiographic (ECG) monitor. Interference with cardiac pacemaker activity may occur.⁶⁸

Skin burns are the most frequently reported complication in use. Rarely are they fatal, but they are painful and may require skin grafts, raising the possibility of litigation. The burn site can be at the dispersive electrode, ECG monitoring leads, esophageal or rectal temperature probes, or areas of body contact with grounded objects. The dispersive electrode should be firmly attached to a broad area of dry, hairless skin, preferably over a large muscle mass.^{67,68}

Alcohol-based hair care products should be avoided during head and neck surgery because the risk of combustion during the use of electrocautery.

Preparation of the OR should include verification of the proper function and grounding of the unit and proper placement of the dispersive electrode. Smoke evacuators are highly recommended. The National Institute for Occupational Safety and Health (NIOSH) recommends a system that can pull 50 cubic feet per minute with a capture velocity of 100 to 150 feet per minute at the inlet nozzle and positioned within 2 inches of the surgical site.⁶⁹ Filters should be installed to capture the contents of the smoke. Used filters are deemed biohazardous. Routine, unfiltered suction is not adequate for this purpose.⁶⁹

LASERS AND LASER SAFETY

Lasers generate focused energy. They have been implicated in skin burns, retinal injuries, endotracheal tube fires, pneumothorax, and damage to viscera and the vasculature.⁷⁰ Both patients and staff have suffered injuries.

The laser-safe OR requires specific modifications. The OR should not have windows. Walls, ceilings, and equipment should be nonreflective. Equipment used in the operative field should be nonreflective and nonflammable. A sign warning personnel that a laser is in use should be posted.

Anesthetic technique should also take the use of lasers into consideration. When lasers are used in the vicinity of the face, airway, or chest cavity, the concentration of O₂ and N₂O in the inhaled gases should be reduced to decrease the possibility of fire. Personnel should wear appropriate eye protection. A smoke evacuator will improve visualization, reduce objectionable odor, and decrease the potential for papillomavirus infection or ingestion of toxic fumes from the laser smoke plume.^{65,71-74}

Table 2 Devices Used in the Operating Room

<i>Function</i>	<i>Device</i>
Support of patient	Anesthesia delivery devices Ventilator Physiologic monitoring devices Warming devices IV fluid warmers and infusers
Support of surgeon	Sources of mechanical, electrical, and internal power, including power tools and electrocautery, as well as laser and ultrasound instruments Mechanical retractors Lights mounted in various locations Suction devices and smoke evacuators Electromechanical and computerized assistive devices, such as robotic assistants Visualization equipment, including microscopes, endoscopic video cameras, and display devices such as video monitors, projection equipment, and head-mounted displays Data, sound, and video storage and transmission equipment Diagnostic imaging devices (e.g., for fluoroscopy, ultrasonography, MRI, and CT)
Support of OR team	Surgical instruments, usually packaged in case carts before each operation but occasionally stored in nearby fixed or mobile modules Tables for display of primary and secondary surgical instruments Containers for disposal of single-use equipment, gowns, drapes, etc. Workplace for charting and record keeping Communication equipment

CT = computed tomography; IV = intravenous; MRI = magnetic resonance imaging; OR = operating room.

POWERED DEVICES

The surgical table must be properly positioned and adjusted to ensure the safety of the patient and the efficient work of the surgical team. Manually adjustable tables are simple, but those with electrical controls are easier to manage. OR table attachments, such as the arm boards and leg stirrups used to position patients, must be properly maintained and secured to prevent injuries to patients or staff. During transfer to and from the OR table, care must be taken to ensure that the patient is not injured and that life support, monitoring, and intravenous (IV) systems remain connected. Proper transfer technique, adequate staff, and the use of assistive devices such as rollers will help prevent musculoskeletal injuries to the OR staff during this maneuver. Patients with fragile skin, including infants, small children, the ill, and the elderly, should be lifted and not dragged into position.

Other powered surgical instruments common in the OR include those used to obtain skin grafts, open the sternum and the cranium, and perform orthopedic procedures. Powered saws and drills can aerosolize body fluids, thereby creating a potential infection and contamination hazard for OR personnel.⁷⁵

OPERATING MICROSCOPE

Microsurgery is a routine part of many surgical specialties, including neurosurgery, plastic surgery, hand surgery, gynecologic surgery, and ophthalmology. Microscopes may be moved into the OR on wheeled stands or mounted on the ceiling, wall, or floor. Built-in microscopes are best employed in dedicated ORs.⁴⁶ All controls and displays must be properly positioned at or below the user's line of sight to allow comfortable and unobstructed viewing.

Modern operating microscopes are servo controlled and counterbalanced. The sequence for properly balancing a microscope should be carefully followed prior to every procedure and each time accessories are added or removed.

Improperly balanced instruments have been known to twist or fall, causing injury to patients and staff.

Many commercial microscope drapes are available. Where the laser is mounted to the microscope, it is essential to confirm that the drape is out of the line of fire to avoid contamination, melting, or kindling.

INTRAOPERATIVE IMAGING AND NAVIGATION

The advent of less invasive surgery requires accurate intraoperative confirmation of surgical anatomy through the use of x-ray, CT, MRI, and ultrasonography. These modalities are increasingly accompanied by and aligned with the use of surgical navigation systems. Intraoperative ultrasonography requires a high-quality portable ultrasound unit and specialized probes. Depending on the procedure and the training of the surgeon, the presence of a radiologist and an ultrasound technician may be requested.

The ultrasound unit should be positioned near the patient, and the surgical team must be able to view the image comfortably. In some cases, the image may be displayed on OR monitors by means of a video mixing device. Ultrasound units may also be used to modify the reference image in real time in surgical navigation systems.⁷⁶

Fluoroscopic and x-ray units may be portable or dedicated. Open radiologic units are usually installed either in the OR proper or immediately adjacent to the OR to permit intraoperative imaging of the selected body area. Intraoperative angiography and MRI devices are typically installed in dedicated ORs.⁷⁷ Intraoperative CT for neurosurgery, for example, may involve either portable or fixed devices.⁷⁸

The use of sequential compression stockings has become the standard of care for the prevention of venous thromboembolism in the majority of operations for which direct access to the lower extremities is not required [see 6:6 *Venous Thromboembolism*].⁷⁹ The air pump often must be placed near the patient on the floor or on a nearby cart. The pressure

tubing from the stockings to the pump must be carefully routed so as not to interfere with surgical access.

Suction devices are ubiquitous in the OR. A typical suction apparatus consists of a set of canisters on a wheeled base receiving suction from a wall- or ceiling-mounted source. The surgeon's aspirating cannula is connected sterilely to these canisters. Suction tubing is a common tripping hazard in the OR. In some procedures, the suction canisters may require repeated changing.

EQUIPMENT

Imaging Equipment

Imaging equipment for endovascular surgery can be fixed to the ceiling or portable. The fixed system is also employed in catheterization laboratories and dedicated interventional radiology suites. Portable systems use C-arms with dedicated vascular software packages designed for optimal endovascular imaging. Each of these systems has advantages and disadvantages.

Fixed ceiling-mounted systems have higher power output and smaller focal spot size and provide the highest-quality images. Larger image intensifiers (up to 16 in.) make possible larger visual fields for diagnostic arteriograms. Fewer runs are necessary, with the advantage of reducing the quantity of contrast injected and radiation exposure.

Fixed systems are accompanied by floating angiography tables, which allow the surgeon to move the patient easily beneath the fixed image intensifier. The variable distance between the x-ray tube and the image intensifier allows the intensifier to be placed close to the patient if desired, thereby improving image quality and decreasing radiation scatter. It is generally accepted that such systems afford the surgeon the most control and permit the most effective imaging of patients.

Fixed ceiling-mounted systems are quite expensive (typically \$1 to \$1.5 million), and major structural renovations are often required for installation in a typical OR. These systems are not particularly flexible. The floating angiography tables and the immobility of the image intensifiers render the rooms unsuitable for most conventional open surgical procedures. As a result, fixed imaging systems are generally restricted to high-volume centers where use rates justify the construction of dedicated endovascular ORs.

The imaging capability and versatility of portable digital C-arms have increased dramatically. State-of-the-art portable C-arms are considerably less expensive than fixed systems (\$175,000 to \$225,000) while retaining many of their advantages. The variable image intensifier size (from 6 to 12 in.) offers valuable flexibility, with excellent resolution at the smaller end and an adequate field of view at the larger end. With some portable C-arm systems, it is possible to vary the distance between the image intensifier and the x-ray tube, as with a fixed system (see above). Pulsed fluoroscopy, image collimation, and filtration are standard features for improving imaging and decreasing radiation exposure. Sophisticated software packages allow high-resolution digital subtraction angiography, variable magnification, road mapping (i.e., the superimposition of live fluoroscopy over a saved digital arteriogram), image fusion, and a number of other useful features. Improvements in C-arm design allow the surgeon to

use a foot pedal to select various imaging and recording modes and to play back selected images and sequences.

Unlike fixed systems, which require patients to be moved on a floating table to change the field of view, C-arm systems require the image intensifier to be moved from station to station over a fixed patient. Although more cumbersome than fixed systems, the newest C-arms have increased mobility and maneuverability. Patients must be placed on a special nonmetallic carbon fiber table. To provide a sufficient field of view and permit panning from head to toe, the tables must be supported at one end and completely clear beneath. Although these tables do not flex, they are sufficient for most operations. Furthermore, they are mobile and may be replaced with conventional operating tables when the endovascular suite is being used for standard open surgical procedures.

Interventional Equipment

The performance of endovascular procedures in the OR requires familiarity with a wide range of devices that may be unfamiliar to OR personnel. These include guidewires, sheaths, specialized catheters, angioplasty balloons, stents, and stent grafts [see Table 3]. In a busy endovascular OR, much of this equipment must be stocked for everyday use, with the remainder ordered on a case-by-case basis. The expense of establishing the necessary inventory of equipment can be substantial and can place a considerable burden on smaller hospitals that are already spending sizable amounts on stocking similar devices for their catheterization laboratories and interventional suites. Fortunately, many companies are willing to supply equipment on a consignment and case basis, allowing hospitals to pay for devices as they are used and reducing the volume of devices stocked.

ORs in Other Specialties

Specialty equipment is generally available for permanent installation in ophthalmologic, orthopedic, trauma, neurosurgical, and urologic ORs. The observations offered regarding microscopes, imaging devices and lasers, storage, and physical layout are broadly applicable. The cardiovascular OR and the neurosurgical OR often have complex needs that are more difficult to fill simply by equipping a general-purpose OR. Thus, a neurosurgical OR may need to be equipped for neuronavigation, laser and microsurgery, intraoperative angiography, neurointerventional surgery, and pediatric surgery. In addition, it may need shielding for neurophysiologic recordings necessary for cranial electrostimulation. The presence of fixed or mounted instrumentation per se rarely poses an insurmountable difficulty in adapting a general-purpose OR to specialty use, but the reverse is not the case.

Surgeon's Control of Equipment: Touch Panels, Voice Activation, and Robotics

Inherent shortcomings in the design of OR equipment have been exacerbated by the spread of minimally invasive procedures. Because most of the equipment needed for minimally invasive surgery resides outside the sterile field, the circulating nurse becomes the point person for critical control. Often the circulating nurse is out of the room at the precise moment important equipment adjustments must be made.

Surgeons grow frustrated at the inevitable delays that follow, and nurses often weary of these additional and sometimes distracting responsibilities. As a result, there is great

Table 3 Standard Equipment for Endovascular Operating Rooms

Diagnostic arteriography	Entry needle (16-gauge beveled) Entry wire (J wire or floppy-tip wire) Arterial sheath (5 Fr) Catheters Multipurpose nonselective (pigtail, tennis racquet, straight, etc.) Selective (cobra head, shepherd's crook, etc.) Guidewires (floppy, steerable, angled, hydrophilic, etc.) Contrast agent (nonionic preferred) Power injector

Endovascular aneurysm repair	Large-caliber sheaths (12–24 Fr) Super-stiff guidewires Endovascular stent grafts Main body and contralateral iliac limb Aortic and iliac extension grafts Endovascular arterial coils

interest in improving the interface of surgical devices with the surgeon. Sterile touchscreens offered the first solution, but many two-handed surgical procedures still make it difficult for a surgeon to control ancillary equipment manually. Voice activation technology offers a potential solution.

Development of voice activation began in the late 1960s. The goal was a simple, safe, and universally acceptable voice recognition system that flawlessly carried out the verbal requests of the user. However, attempts to construct a system capable of accurately recognizing a wide array of speech patterns faced formidable technological hurdles that are only now beginning to be overcome.

In 1998, the first Food and Drug Administration (FDA)-approved voice activation system, Hermes (Computer Motion, Santa Barbara, CA), was introduced into the OR. Designed to provide surgeons with direct access and control of surgical devices, Hermes is operated via either a handheld pendant or voice commands from the surgeon. The challenges of advanced laparoscopic surgery provide a fertile ground for demonstrating the benefits of voice activation [see *Table 4*].

Voice activation offers surgeons immediate access to and direct control of surgical devices. At the same time, it

provides the OR team with critical information about the progress of the operation. To operate a device, the surgeon must take approximately 20 minutes to train the recognition system to his or her voice patterns and must wear an audio headset to relay commands. The learning curve for voice control is minimal (two or three cases, on average). Devices that can now be controlled by voice activation software include cameras, light sources, digital image capture and documentation devices, printers, insufflators, OR ambient and surgical lighting systems, operating tables, and electrocauteries.

Infection Control in the OR

Infection control is a major concern in health care in general, but it is a particularly important issue in the sterile environment of the OR, where patients undergo surgical procedures and are at significant risk for perioperative nosocomial infection. Even the best OR design will not compensate for improper surgical technique or failure to pay attention to infection prevention.

Surgical site infection (SSI) is a major cause of patient morbidity, mortality, and health care costs. In the United States, according to the Centers for Disease Control and Prevention (CDC), approximately 2.9% of nearly 30 million

Table 4 Benefits of Voice Activation Technology in the Laparoscopic Operating Room

Benefits to surgical team	Gives surgeons direct and immediate control of devices Frees nursing staff from dull, repetitive tasks Reduces miscommunication and frustration between surgeons and staff Increases OR efficiency Alerts staff when device is malfunctioning or setting off alarm
Benefits to hospital	Saves money, allowing shorter, more efficient operations Contributes to better OR use and, potentially, performance of more surgical procedures Lays foundation for expanded use of voice activation in ORs Allows seamless working environment
Benefit to patient	Reduces operating time, which—coupled with improved optics, ergonomics, and efficiency—leads to better surgical outcome

OR = operating room.

operations are complicated by SSIs each year. This percentage may, in fact, be an underestimate, given the known inherent problems with surgeons' voluntary self-reporting of infections occurring in the ambulatory surgical setting.⁸⁰ Each infection is estimated to increase total hospital stay by several days and add materially to costs and charges.

SSIs pose an increasingly difficult problem for institutions with a large Medicare population. Recently, the Centers for Medicare and Medicaid Services (CMS) published the Inpatient Prospective Payment System (IPPS) FY 2009 final rule expanding the list of hospital-acquired conditions (HACs) that will reduce Medicare payments. A number of SSIs figure prominently on this list.⁸¹ State Medicaid directors have also been authorized to deny payment for certain HACs.

The epidemiology and management of SSIs in older adults are receiving increasing attention.⁸² SSIs have been divided by the CDC into three broad categories: superficial incisional SSI, deep incisional SSI, and organ or space SSI [see Table 5 and 1:1 *Prevention of Postoperative Infection*].⁸³

Factors that contribute to the development of SSI include (1) the patient's health status, (2) the physical environment where surgical care is provided, and (3) clinical interventions that increase the patient's inherent risk. Careful patient selection and preparation, including judicious use of antibiotic prophylaxis, can decrease the overall risk of infection, especially after clean-contaminated and contaminated operations.

HAND HYGIENE

Hand antisepsis plays a significant role in preventing nosocomial infections. When outbreaks of infection occur in the perioperative period, careful assessment of the adequacy of hand hygiene among OR personnel is important. Agents used for surgical hand scrubs should substantially reduce microorganisms on intact skin, contain a nonirritating antimicrobial preparation, possess broad-spectrum activity, and be fast-acting and persistent.⁸⁴ The CDC offers the following guidelines⁸⁵:

- Surgical hand antisepsis using either an antimicrobial soap or an alcohol-based hand rub with persistent activity is recommended before donning sterile gloves when performing surgical procedures (evidence level IB).
- When performing surgical hand antisepsis using an antimicrobial soap, scrub hands and forearms for the length of time recommended by the manufacturer, usually 2 to 6 minutes. Long scrub times (e.g., 10 minutes) are not necessary (evidence level IB).
- When using an alcohol-based surgical hand-scrub product with persistent activity, follow the manufacturer's instructions. Before applying the alcohol solution, prewash hands and forearms with a nonantimicrobial soap and dry hands and forearms completely. After application of the alcohol-based product, allow hands and forearms to dry thoroughly before donning sterile gloves.

GLOVES AND PROTECTIVE BARRIERS

There is a high risk of pathogen transfer during surgery. This is a risk from which both the patient and the surgical team must be protected. The risk can be reduced by using protective barriers, such as surgical gloves. Wearing two pairs

of surgical gloves rather than a single pair provides an additional barrier and further reduces the risk of contamination. A 2002 Cochrane Review concluded that wearing two pairs of latex gloves significantly reduced the risk of hand exposure. The rate of single-glove perforations is approximately 15%. The rate of inner glove perforation when two pairs of gloves are worn is approximately 5%.⁸⁶

OSHA requires that personal protective equipment be available in the health care setting, and these requirements are specified in the OSHA standard on occupational exposure to bloodborne pathogens, which went into effect in 1992. Among the requirements is the implementation of the CDC's universal precautions, designed to prevent transmission of HIV, hepatitis B virus, and other bloodborne pathogens.⁸⁷ These precautions dictate the use of protective barriers (e.g., gloves, gowns, aprons, masks, and protective eyewear) to reduce the risk that the health care worker's skin or mucous membranes will be exposed to potentially infectious materials.

Performance standards for protective barriers are the responsibility of the FDA's Center for Devices and Radiological Health. FDA standards define the performance properties that these products must exhibit, including minimum strength, barrier protection, and fluid resistance. The current CDC recommendation is to use surgical gowns and drapes that resist liquid penetration and remain effective barriers when wet.

These standards are intuitively appealing, but few studies address the comparative benefits of specific types of drapes. A meta-analysis of over 5,000 surgical cases indicated that adhesive drapes increase the risk of SSI (relative risk = 1.23; $p = .03$) and iodine-impregnated drapes had no effect.⁸⁸

Compliance with universal precautions and barrier protection is a challenge. Educational efforts aimed at OR personnel improved compliance significantly, particularly with regard to the use of protective eyewear and double-gloving. These efforts were associated with a reduced incidence of blood and body fluid exposure.⁸⁹

ANTIMICROBIAL PROPHYLAXIS

SSIs are established several hours after contamination.⁹⁰ There is a well-recognized "golden period" during which prophylactic antibiotics can be effective. Administration of antibiotics before contamination reduces the risk of infection but is subsequently of little value.⁹¹ Selective use of short-duration, narrow-spectrum antibiotic agents should be considered for appropriate patients to cover the usual pathogens isolated from SSIs [see Table 6].⁹²

Recommendations for antibiotic prophylaxis are addressed in more detail elsewhere [see 1:1 *Prevention of Postoperative Infection*]. In brief, the principles of optimal surgical antimicrobial prophylaxis include (1) appropriate choice of an antimicrobial agent, (2) proper timing of antibiotic administration before incision, and (3) limited duration of antibiotic administration after operation.

When a preoperative antibiotic is indicated, a single dose of therapeutic strength, administered shortly before incision, usually suffices.⁹³ The dose may have to be increased if the patient is morbidly obese.⁹⁴ A second dose is indicated if the procedure is longer than two half-lives of the drug or if extensive blood loss occurs. Continuation of prophylaxis beyond 24 hours is not recommended.

Table 5 Criteria for Defining a Surgical Site Infection⁸³

Superficial incisional SSI

Infection occurs within 30 days after the operation, *and* infection involves only skin or subcutaneous tissue of the incisions, *and* at least *one* of the following:

1. Purulent drainage, with or without laboratory confirmation, from the superficial incision
2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision
3. At least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat; *and* superficial incision is deliberately opened by surgeon, *unless* incision is culture negative
4. Diagnosis of superficial incisional SSI by the surgeon or attending physician

Do *not* report the following conditions as SSI:

1. Stitch abscess (minimal inflammation and discharge confined to the points of suture penetration)
2. Infection of an episiotomy or newborn circumcision site
3. Infected burn wound
4. Incisional SSI that extends into the fascial and muscle layers (see deep incisional SSI)

Note: Specific criteria are used for identifying infected episiotomy and circumcision sites and burn wounds.

Deep incisional SSI

Infection occurs within 30 days after the operation if no implant* is left in place or within 1 yr if an implant is in place and the infection appears to be related to the operation, *and* infection involves deep soft tissues (e.g., fascial and muscle layers) on the incision, *and* at least *one* of the following:

1. Purulent drainage from the deep incision but not from the organ/space component of the surgical site
2. A deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs or symptoms: fever ($> 38^{\circ}\text{C}$ [100.4°F]), localized pain, or tenderness, unless the site is culture negative
3. An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination
4. Diagnosis of a deep incisional SSI by a surgeon or attending physician

Notes

1. Report infection that involves both superficial and deep incision sites as deep incisional SSI
2. Report an organ/space SSI that drains through the incision as a deep incisional SSI

Organ/space SSI

Infection occurs within 30 days after the operation if no implant* is left in place or within 1 yr if an implant is in place and the infection appears to be related to the operation, *and* infection involves any part of the anatomy (e.g., organs or spaces), other than the incision, which was opened or manipulated during an operation, *and* at least *one* of the following:

1. Purulent drainage from a drain that is placed through a stab wound[†] into the organ/space
2. Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space
3. An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination
4. Diagnosis of an organ/space SSI by a surgeon or attending physician

SSI = surgical site infection.

*National Nosocomial Infection Surveillance definition; a non-human-derived implantable foreign body (e.g., prosthetic heart valve, nonhuman vascular graft, mechanical heart, or hip prosthesis) that is permanently placed in a patient during surgery.

[†]If the area around a stab wound becomes infected, it is not an SSI. It is considered a skin or soft tissue infection, depending on its depth.

The provision of prophylactic antibiotics, where indicated, has been accepted as a measure of surgical quality aimed at a reduction in SSIs.^{95,96} A strong economic case has been made for infection control, including prophylactic antibiotics, benefiting the hospital as well as the patient.⁹⁷ The perioperative nursing team has a central role, together with the anesthesiologist, in monitoring the administration of preoperative prophylactic antibiotics.^{98–100}

NONPHARMACOLOGIC PREVENTIVE MEASURES

Several studies have confirmed that certain nonpharmacologic measures, including maintenance of perioperative normothermia and provision of supplemental perioperative oxygen, are efficacious in preventing SSIs.¹⁰¹

Perioperative Normothermia

A 1996 study showed that warming patients during colorectal surgery reduced infection rates.¹⁰² This finding was confirmed in a subsequent observational cohort study that reported a significantly increased incidence of SSI with hypothermia.¹⁰³ A randomized, controlled trial of 421 patients,

published in 2001, determined that warming patients before short-duration clean procedures (breast, varicose vein, or hernia) reduced infection ($p = .001$) and reduced wound scores ($p = .007$) in this setting as well.¹⁰⁴

The safest and most effective way of protecting patients from hypothermia is to use forced-air warmers with specialized blankets placed over the upper or lower body. Alternatives include placing a warming water mattress under the patient and draping the patient with an aluminized blanket. Second-line therapy involves warming all IV fluids. Any irrigation fluids used in a surgical procedure should be at or slightly above body temperature before use. Radiant heating devices placed above the operative field may be especially useful during operations on infants. Use of a warmer on the inhalation side of the anesthetic gas circuit can also help maintain the patient's body temperature during an operation.

Supplemental Perioperative Oxygen

Destruction by oxidation, or oxidative killing, is the body's most important defense against surgical pathogens. This

Table 6 Distribution of Pathogens Isolated from Surgical Site Infections: National Nosocomial Infections Surveillance System, 1986–1996⁸³

Pathogen	Percentage of Isolates*	
	1986–1989 (N = 16,727)	1990–1996 (N = 17,671)
<i>Staphylococcus aureus</i>	17	20
Coagulase-negative staphylococci	12	14
<i>Enterococcus</i> species	13	12
<i>Escherichia coli</i>	10	8
<i>Pseudomonas aeruginosa</i>	8	8
<i>Enterobacter</i> species	8	7
<i>Proteus mirabilis</i>	4	3
<i>Klebsiella pneumoniae</i>	3	3
Other <i>Streptococcus</i> species	3	3
<i>Candida albicans</i>	2	3
Group D streptococci (nonenterococci)	—	2
Other gram-positive aerobes	—	2
<i>Bacteroides fragilis</i>	—	2

*Pathogens representing less than 2% of isolates are excluded.

defensive response depends on oxygen tension in contaminated tissue. An easy method of improving oxygen tension in adequately perfused tissue is to increase the FiO_2 . Supplemental perioperative oxygen (i.e., an FiO_2 of 80% instead of 30%) significantly overcomes the decrease in phagocytosis and bacterial killing usually associated with anesthesia and surgery (and significantly reduces postoperative nausea and vomiting). Oxygen tension in wound tissue has been found to be a good predictor of SSI risk.¹⁰⁵

Avoidance of Blood Transfusion

The association between blood transfusion and increased perioperative infection rates is well documented. In a 1997 study, geriatric hip fracture patients undergoing surgical repair who received blood transfusion had significantly higher rates of perioperative infection than those who did not (27% versus 15%), and this effect was confirmed on multivariate analysis.¹⁰⁶ Another study yielded similar findings in colorectal cancer: the relative risk of infection was 1.6 for transfusion of one to three units of blood and 3.6 for transfusion of more than three units.¹⁰⁷

A large prospective cohort study published in 2003 evaluated the association between anemia, blood transfusion, and perioperative infection.¹⁰⁸ Regression analysis confirmed that intraoperative transfusion of packed red blood cells was an independent risk factor for perioperative infection (odds ratio 1.06; confidence interval 1.01 to 1.11; $p > .0001$). Furthermore, transfusion of more than four units of packed red blood cells was associated with a ninefold increased risk of infection (confidence interval 5.74 to 15.00; $p < .0001$).

Tight Glycemic Control

Hyperglycemia is common under conditions of physiologic stress, in the intensive care unit (ICU) and in the OR. Tight glycemic control using intensive insulin therapy and continuous glucose monitoring has been shown to reduce infection in the ICU and is emerging as a standard in surgical critical care and intraoperatively.^{109,110} It has been associated with a

decrease in mortality rate generally in critically ill patients.^{111,112} The effects are not restricted to diabetics. In fact, there is evidence to conclude that nondiabetics enjoy more protection than diabetics.¹¹³

Some questions remain about just how tight control must be to have an effect. There is a small but measurable risk of hypoglycemia with intensive IV insulin therapy, but this risk can be mitigated with continuous or near-continuous glucometry or dynamic scale nomograms.¹¹⁴

Housekeeping Procedures

FLOORS AND WALLS

Despite detailed recommendations for cleaning the OR [see Table 7], the procedures that are optimal to provide a clean environment while still being cost-effective have not been critically analyzed.¹¹⁵

Only a few studies have attempted to correlate surface contamination of the OR with SSI risk. In one randomized, controlled study, for example, the control rooms were cleaned with a germicidal agent and wet-vacuumed before the first case of the day and between cases, whereas in the experimental rooms, cleaning consisted only of wiping up grossly visible contamination after clean and clean-contaminated cases.¹¹⁶ Both rooms had complete floor cleanup after contaminated or dirty and infected cases. Bacterial colony counts obtained directly from the floors were lower in the control rooms, but counts obtained from other horizontal surfaces did not differ between the two OR groups. Wound infection rates were the same in the control rooms and the experimental rooms and were comparable with rates reported in other series.

Another study found that floor disinfectants decreased bacterial concentration on the floor for 2 hours only. Colony counts return to pretreatment levels as personnel walked about.¹¹⁷

Even when an OR floor is contaminated, the rate of redispersal of bacteria into the air is low, and the clearance rate is

Table 7 Operating Room Cleaning Schedules

Areas requiring daily cleaning	Surgical lights and tracks Fixed ceiling-mounted equipment Furniture and mobile equipment, including wheels OR and hall floors Cabinet and push-plate handles Ventilation grills All horizontal surfaces Substerile areas Scrub and utility areas Scrub sinks
Areas requiring routinely scheduled cleaning	Ventilation ducts and filters Recessed tracks Cabinets and shelves Walls and ceilings Sterilizers, warming cabinets, refrigerators, and ice machines

OR = operating room.

high. It seems unlikely, therefore, that bacteria from the floor contribute to SSI. Consequently, routine disinfection of the OR floor between clean or clean-contaminated cases appears to be unnecessary.

According to CDC guidelines for the prevention of SSI, when visible soiling of surfaces or equipment occurs during an operation, an Environmental Protection Agency (EPA)-approved hospital disinfectant should be used to decontaminate the affected areas before the next operation.⁸³ This statement is in keeping with the OSHA requirement that all equipment and environmental surfaces be cleaned and decontaminated after contact with blood or other potentially infectious materials.

Disinfection after a contaminated or dirty case and after the last case of the day is probably a reasonable practice, although it is not supported by directly pertinent data. Wet-vacuuming of the floor with an EPA-approved hospital disinfectant should be performed routinely after the last operation of the day or night.

DIRTY CASES

Operations are classified or stratified into four groups in relation to the epidemiology of SSIs [see 1:1 *Prevention of Postoperative Infection*]¹¹⁸:

- Clean operations are those elective cases in which the gastrointestinal (GI) tract or the respiratory tract is not entered and there are no major breaks in technique. The infection rate in this group should be less than 3%.
- Clean-contaminated operations are those elective cases in which the respiratory or the GI tract is entered or during which a break in aseptic technique has occurred. The infection rate in such cases should be less than 10%.
- Contaminated operations are those cases in which a fresh traumatic wound is present or gross spillage of GI contents occurs.
- Dirty or infected operations include those in which bacterial inflammation occurs or in which pus is present. The infection rate may be as high as 40% in a contaminated or dirty operation.

Fear that bacteria from dirty or heavily contaminated cases could be transmitted to subsequent cases has resulted in the

development of numerous and costly rituals of OR cleanup. However, there are no prospective studies and no large body of relevant data to support the usefulness of such rituals. In fact, one study found no significant difference in environmental bacterial counts after clean cases than after dirty ones.¹¹⁹ Numerous authorities have recommended that there be only one standard of cleaning the OR after either clean or dirty cases.^{115,119,120} This recommendation is reasonable because of two important considerations:

- Any patient may be a source of contamination caused by unrecognized bacterial or viral infection.
- The second major source of OR contamination is the personnel who work there.

Rituals applied to dirty cases include placing a germicide-soaked mat outside the OR door, allowing the OR to stand idle for an arbitrary period after cleanup of a dirty procedure, and using two circulating nurses, one inside the room and one outside. None of these practices has a sound theoretical or factual basis.

By tradition, dirty cases are scheduled after all of the clean cases of the day have been completed. This restriction, however, reduces the efficiency with which operations can be scheduled and may unnecessarily delay emergency cases. There are no data to support special cleaning procedures or the closing of an OR after a contaminated or dirty operation has been performed.¹²¹ Mats placed outside the entrance to the OR suite show neither a reduction in the number of organisms on shoes and stretcher wheels nor a reduction in SSI risk.¹²²

Data Management in the OR

Regular analysis of OR data is essential to monitor efficiency and correct deficiency.¹²³ OR efficiency is maximized by adherence to several basic principles:

1. The number of ORs available should be matched to the number required to achieve good use.
2. Nurses and anesthesiologists rather than attending surgeons should control access to the surgical schedule.
3. Surgeons should be allowed to follow themselves.

4. Block time should be provided to surgeons.
5. Systems should be established to enable and enforce efficient turnover between cases.¹²⁴

The distinction between efficiency and effectiveness is important. Measures of effectiveness relate achievements to goals. Measures of efficiency relate achievements to cost. The OR must be both efficient and effective.

Data must be both available and rapidly accessible. Automation of OR data is critical and must integrate with the institutional health information system (HIS).¹²⁵ Hospital-wide data regarding work flow, staffing, referral patterns, and even parking may yield useful information for improvements in OR efficacy and efficiency.¹²⁶

OR SCHEDULING

OR scheduling systems should be designed to track all of the operational aspects of the OR, including patients, resources, rooms, and staff. They should be fully integrated into the institutional HIS while also interfacing with key elements located in other parts of the hospital (or ambulatory center), including finance, materials management, electronic medical records, radiology, pathology, nursing, the emergency room, labor and delivery, the blood bank, and the pharmacy.

One of the most important purposes of a good OR scheduling system is to allow informed case substitution. Informed case substitution is critical because surgical scheduling must contend with frequent last-minute case cancellations.¹²⁷ Different specialties differ widely in their scheduling practices. An understanding of these practices allows the OR to use resources to maximum efficiency.¹²⁸

Information systems that predict and fill unexpected openings already exist in the transportation and manufacturing

industries. In the future, such technology may be a useful adjunct to computerized OR scheduling.¹²⁷

QUALITY IMPROVEMENT

The key to increased OR efficiency is increased productivity. Standardization of internal procedures reduces bottlenecks. Computerization speeds the flow of information so that continuous improvement of the system becomes possible. Before a desired improvement can be implemented, the proposed change must be tested quickly so that its effect can be determined, ideally through a small-scale pilot implementation. This requires a collaborative effort, in which the group involved in the change learns how to “plan, do, check, and act.” These are the elements of the so-called “PDCA cycle,” a classic quality initiative method. During the PDCA cycle, teams are encouraged to strategize and communicate about various solutions and look for changes that can be made. A change is tested, quickly evaluated, and adopted if efficacious. The PDCA cycle depends on integrated surgical teams with open communication and mutual respect. Such teams remain the key to a safe, efficient, and effective OR.⁸⁹

Dr. Dagi is a director for Acela, Inc. and IntelliDx, Inc. His personal investment portfolio includes pharmaceutical and medical device companies, none of whose products have been mentioned in this chapter. He chairs the Scientific Advisory Board for Dupont life sciences. He has received neither financial nor research support from any of these entities.

Dr Schechter has no significant financial or other relationships with pharmaceutical, medical device, or biologics companies relevant to this chapter.

De Maria, MD, FACS, and Lena M. Napolitano, MD, FACS, FCCM, who wrote and edited this chapter for the previous version of *ACS Surgery*. This chapter has drawn heavily on their work and generally follows their outline and concept of the subject discussed. Russell Stewart contributed to the research and bibliography.

9 FAST TRACK INPATIENT AND AMBULATORY SURGERY

Liane Feldman, MD, FACS, FRCS, and Franco Carli, MD, PhD, FRCA, FRCPC

Fast track (also known as accelerated recovery, accelerated rehabilitation, enhanced recovery, or multimodal rehabilitation) surgery involves the use of a coordinated, multidisciplinary perioperative care plan to reduce complications, facilitate earlier discharge from the hospital, and permit faster recovery of the ability to carry out daily activities after elective surgery.¹ This approach is the result of advancements in anesthetic techniques, improved understanding of perioperative organ dysfunction, and the introduction of minimally invasive surgery (MIS). Attenuation of the stress response to surgery (endocrine, metabolic and immunologic) and consequent prevention of some of its negative effects (e.g., increased cardiac demands, decreased gastrointestinal [GI] motility, and pain) underlie many of the benefits of fast track surgery.²

A unifying theme in the development and implementation of fast track surgery is the quest to understand and address the factors that keep patients hospitalized after major surgery and impede their return to baseline performance and function.³ These interrelated factors include the need for parenteral analgesia, the requirement for intravenous (IV) fluids, and lack of mobility.⁴ Whereas some of these factors have a physiologic basis (e.g., decreased GI motility from the sympathetic response to surgery), others are related to traditions or cultural aspects of the care of surgical patients (e.g., waiting for GI motility to return before introducing oral intake). The goal is to combine a variety of individual evidence-based elements of perioperative care, each of which may have only modest benefits when used in isolation, into a coordinated effort that can be expected to have a synergistic beneficial effect on surgical outcomes.⁵ The term fast track has contributed to the misconception that the primary goal of this approach is cost containment through the reduction of hospital stay; however, the primary goals are in fact to shorten recovery time, decrease morbidity, and improve efficiency.^{6,7} The principles of fast track surgery are applicable to both outpatient and inpatient procedures: many procedures that once necessitated hospitalization are now routinely performed in an ambulatory or short-stay setting.

A fast track surgery program encompasses preoperative, intraoperative, and postoperative phases. The principal elements are as follows.

1. Preoperative patient education and preparation for surgery (“prehabilitation”).
2. Newer anesthetic, analgesic, and surgical techniques, whose aim is to decrease the surgical stress response, pain and discomfort, and postoperative nausea and vomiting.
3. Aggressive postoperative rehabilitation, including early enteral feeding and ambulation. This also includes changes

in the traditional surgical practice concerning the use of drains, tubes and catheters.

Some of these individual elements may be part of evidence-based modern surgical care, but there remains a great deal of variability among surgeons and institutions.⁸ Introduction of one or more components in isolation may improve some specific outcomes, but the underlying hypothesis in fast track surgery is that a multimodal approach to care will enhance outcomes further.⁴ Although few data are available, the existing evidence is encouraging and suggests that fast track programs are associated with reductions in hospital stay and morbidity.⁶ Successful implementation of a formal fast track program at the institutional level, however, requires significant resources and time and involves an organized and coordinated effort on the part of a motivated multidisciplinary team that includes anesthesiologists, surgeons, nurses, physiotherapists, social workers, nutritionists, and patients. This represents a shift from conventional surgical practice, in which perioperative management is primarily dictated by the surgeon’s preference.

In this chapter, we describe the constituent elements of a fast track surgery program. We review the organizational steps required to set up such a program and provide specific examples of care plans in digestive surgery.

Preoperative Issues

PHYSICAL OPTIMIZATION

Evaluation and Optimization of Preexisting Organ Function

Postoperative complications are related to preoperative comorbid conditions,⁹ including inadequate nutrition.¹⁰ Classification of functional capacity and optimization of organ function are expected to reduce cardiovascular and other complications. The preoperative evaluation is also an opportunity to improve long-term health apart from surgical considerations—for example, by counseling patients who may benefit from long-term beta blockade, smoking cessation, or tightened glycemic control. A substantive discussion of cardiopulmonary risk assessment and reduction is beyond the scope of this chapter; however, various current guidelines and algorithms are available for assessment and reduction of perioperative risk related to cardiac disease,¹¹ pulmonary complications,¹² obesity,¹³ and diabetes.¹⁴

The perioperative period provides smokers with a good opportunity to quit. Smoking increases the risk of cardiac, respiratory, and wound complications,¹⁵ and abstinence reduces complications.^{16,17} Although reduction of pulmonary complications requires an abstinence period of weeks to

months, cardiac and wound complications are reduced after shorter periods.¹⁵ Smokers should be advised to quit and referred to resources that will help them do so.

Assessment and Optimization of Nutritional Status

Poor nutritional status is an independent risk factor for complications after surgery. Patients with moderate and severe preoperative undernutrition benefit from preoperative nutritional support, preferably via the enteral route, for at least 7 days preoperatively.^{10,18} Patients with less severe malnutrition, including those with diminished oral intake as a consequence of their underlying disease, generally benefit from the addition of oral nutritional supplements to their normal diet.

Improvement of Physical Fitness

The perioperative period may be associated with rapid physical deconditioning, requiring a period of recovery during which patients are fatigued and quality-of-life and activities are curtailed. Given that patients with poor baseline exercise tolerance and physical conditioning are at increased risk for serious perioperative complications^{11,19} and prolonged disability,^{20,21} it seems reasonable to hypothesize that improving functional capacity by increasing physical activity before surgery may be protective.²² Physical fitness can potentially be improved significantly while patients are waiting for scheduled procedures: modest improvements in aerobic capacity may be seen in older adults after training only 1 hour a day, four times a week, for 4 weeks.²³ The strategy of augmenting physical capacity in anticipation of an upcoming stressor is termed prehabilitation—as opposed to rehabilitation, which begins only after the injury or operation has taken place.

Preliminary evidence supports the use of exercise prehabilitation before surgery. In one study, adults randomly assigned to exercise for 1 month showed faster healing of a punch-biopsy site than control subjects did.²⁴ In another, a preoperative exercise program carried out by patients awaiting lung cancer surgery improved exercise capacity to a degree that mitigated the expected postsurgical decline.²⁵ In yet another study, patients receiving twice-weekly exercise training while waiting for coronary artery bypass graft surgery (CABGS) had shorter hospital stays and better preoperative and postoperative quality of life than control subjects; the quality-of-life differences remained for up to 6 months after surgery.²⁶ Observational data suggest that simply instructing patients to walk 30 minutes daily in the perioperative period may be beneficial, without the need for a formal individualized exercise program (F. Carli and associates, unpublished data).

Preoperative Fasting

To reduce the risk of tracheal aspiration of gastric contents at the induction of general anesthesia, patients have traditionally had to refrain from oral ingestion of both solids and liquids (nil per os [NPO]) from midnight of the night before the operation. This standard approach is convenient and easy to follow, but it requires patients to spend a long period without hydration or nutrition, especially for operations scheduled in the afternoon. Solids may present a risk, but there is no evidence that oral intake of water and other clear fluids (e.g., tea, coffee, apple juice, and pulp-free orange

juice) up to 2 hours preoperatively increases gastric fluid volume or exacerbates the risk of aspiration in otherwise healthy adults.^{27,28} Current preoperative fasting guidelines for adult patients undergoing elective surgery recommend a 2-hour fast for liquids and a 6-hour fast for solids.²⁹ These recommendations do not apply to patients with delayed gastric emptying (e.g., from gastroparesis, GI obstruction, or upper GI tract malignancy).

Preoperative Ingestion of Oral Carbohydrate Drink

That it is safe to administer fluids up to 2 hours before surgery enables the use of high-carbohydrate drinks immediately before operation. Emerging evidence suggests that it may be beneficial to provide a drink containing 100 g of carbohydrate the evening before surgery and a second drink containing a further 50 g 2 to 3 hours before induction of anesthesia. This measure improves preoperative feelings of thirst, hunger, and anxiety³⁰; reduces postoperative insulin resistance; and reduces the catabolic stress response to surgery.³¹ Compared with control subjects, patients receiving preoperative oral carbohydrate drinks had less muscle loss³² and better whole-body protein balance³³ after major abdominal surgery and had shorter hospital stays after colorectal surgery.³⁴ Preoperative carbohydrate drinks reduced nausea and vomiting after laparoscopic cholecystectomy in one trial³⁵ but not in another.³⁶

PATIENT EDUCATION

Preoperative patient education is an essential component of fast track surgery. For many patients, impending major surgery represents a significant psychological stress. Greater preoperative emotional distress, depression, and anxiety are associated with poorer operative outcomes, including increased pain, higher complication rates, poorer wound healing, longer hospital stays, slower return to normal daily activities, and reduced patient satisfaction.^{37,38} There is evidence that emotional distress delays wound healing by altering endocrine and inflammatory responses.^{39,40} The results from meta-analyses suggest that preoperative patient education and preparation have positive effects on certain outcomes (e.g., pain, psychological distress, and indexes of recovery, including hospital stay), even if the intervention is relatively brief and not individualized.⁴⁰ For example, patients who watched a video involving an actor outlining aspects of perioperative care after inguinal hernia surgery experienced improved quality of life and faster resumption of baseline activities in comparison with control subjects.⁴¹

Patient expectation may also play a role in determining postoperative outcome.⁴² Because the fast track recovery program may differ from patients' and caregivers' expectations for and previous experiences with hospitalization and surgery, it is important to specify the active role the patient is expected to play. Such specification includes providing explicit written information about the benefits of the program, the goals for daily nutritional intake and ambulation in the early postoperative period, the discharge criteria, and the expected hospital stay. Information about sensory experiences (e.g., pain, nausea and vomiting, and fatigue) are included in the discussion and the written materials, as well as guidelines regarding what to expect once they leave the hospital.

PREMEDICATION

In the past, preanesthetic medication was administered with the intent of providing sedation and reducing anxiety. Today, with the advent of same-day admission and fast track surgery, premedication may play additional roles, including modulation of intraoperative hemodynamics and attenuation of postoperative side effects.⁴³

Benzodiazepines are excellent anxiolytics that possess rapid onset of action and are flexible in use, being available in both IV and oral forms. Doses as small as 2 mg effectively reduce anxiety and anxiety-related complications.⁴⁴ They also reduce the amount of anesthetic required and provide comfort. Opioids such as morphine and meperidine are no longer for premedicants in outpatient settings, because of the prolonged duration of action and the high incidence of side effects. Fentanyl has a better profile for fast track surgery and facilitates early hospital discharge. Acetaminophen and cyclooxygenase-2 (COX-2) inhibitors (e.g., celecoxib) can be administered either orally or rectally up to 1 hour before surgery and possess significant perioperative opioid-sparing effects.⁴⁵

Anticholinergics (e.g., atropine and scopolamines) are rarely used today, except for procedures such as laryngoscopy or bronchoscopy, in which reduction of secretions is required. These compounds are not given to elderly patients, because they may trigger delirium; rather, glycopyrrolate (0.3 mg IV), which does not cross the blood-brain barrier, is preferred.

Beta blockers and alpha₂ agonists can be used as adjuvants to fast track anesthetic techniques. With their anesthetic and analgesic-sparing effects,^{46–49} these medications maintain perioperative hemodynamic stability and reduce postoperative pain, thus facilitating the early recovery process. Beta blockers (e.g., propranolol, atenolol, labetalol, esmolol) attenuate the intraoperative rise in circulating concentrations of catecholamines, promote hemodynamic stability during emergence from anesthesia and in the early postoperative period, and prevent perioperative cardiovascular events in elderly patients undergoing noncardiac surgery⁵⁰ and patients with preexisting coronary artery disease.^{51,52} In addition, preliminary evidence that beta blockers possess anticatabolic properties and anesthetic and analgesic-sparing effects suggests that they may play a role in accelerating the recovery process.⁵³ Alpha₂ agonists (e.g., clonidine or dexmedetomidine) have also been used as premedicants with the goal of reducing the need for opioid analgesics and attenuating sympathoadrenergic and hypothalamopituitary responses. Clonidine shortens the duration of paralytic ileus after colorectal procedures⁵⁴ and decreases the incidence of postoperative nausea and vomiting (PONV). Both clonidine and dexmedetomidine have been shown to reduce the incidence of myocardial ischemia.⁵⁵

Antacids and H₂-receptor antagonists can be administered before surgery in subjects at risk for gastric aspiration (e.g., those who are diabetic, obese, or pregnant; have gastroesophageal reflux disease; or have sustained a stroke). H₂-receptor antagonists are given the evening before surgery and in the morning to decrease the volume and acidity of gastric content. A nonparticulate antacid (e.g., sodium citrate) is given 1 hour before surgery to raise the gastric pH.

Administration of anti-PONV medications such as dexamethasone and ondansetron before or during the induction and maintenance of anesthesia is recommended in high-risk

subjects and has been shown to facilitate the recovery period and decrease hospital admission after ambulatory surgical procedures.

Intraoperative Issues

ATTENUATION OF SURGICAL STRESS RESPONSE

Surgery initiates a series of metabolic and inflammatory responses that are involved in the pathogenesis of postoperative morbidity and can slow the recovery process. These responses induce a transient but reversible state of insulin resistance, the magnitude of which is linked to the invasiveness of the surgical procedure. This state is characterized by a decrease in peripheral glucose uptake and a concomitant increase in endogenous glucose production. The magnitude of this noxious response can be reduced by perioperative interventions that modify the catabolic response. These interventions can be classified as pharmacologic (high-dose opioids, neural blockade with local anesthetics, beta blockers, glucocorticoids, alpha₂ agonists, nonsteroidal anti-inflammatory drugs [NSAIDs]), hormonal (insulin, growth hormone, estrogens), physical (normothermia, MIS), and nutritional. Among these interventions, intraoperative and postoperative blockade of afferent neural nociceptive stimuli by epidural and spinal block using local anesthetics has been shown to be the most powerful modulator of the metabolic and endocrine stress response. To be effective, however, the neural blockade must be established before surgery and continued for a minimum of 48 hours.⁵⁶

For postoperative pain relief, epidural block achieved with a mixture of local anesthetics and opioids provides excellent postoperative analgesia at rest and during movement compared with systemic opioids,⁵⁷ thus facilitating resumption of dietary intake and utilization of nutrients,⁵⁸ attenuating the loss of body mass, and allowing earlier resumption of exercise.⁵⁹ Epidural block also affects insulin resistance, attenuating the hyperglycemic response, facilitating the oxidative utilization of exogenous glucose,⁶⁰ and thereby preventing the postoperative loss of aminoacids and saving almost 100 g of lean body mass daily.⁶¹ The extent of protein sparing has been found to be greater than that previously achieved with hormonal and nutritional interventions. Epidural block has anticatabolic effects, and patients can be rendered anabolic with the concomitant administration of glucose and aminoacids⁶² or aminoacids alone; the advantage of the latter is that it is not associated with hyperglycemia.^{63–65} Preoperative oral or IV carbohydrate administration also reduces postoperative insulin resistance, thus decreasing postoperative catabolism and resulting in less fatigue.^{66–68}

A single dose of glucocorticoids given at induction of anesthesia decreases the inflammatory response without causing any significant side effects. Beta blockers also reduce cardiac demands and sympathetic stimulation and have been shown to attenuate catabolism in burn patients.⁵³ MIS attenuates the inflammatory response but not the endocrine one. Although it is not clear to what extent MIS modulates catabolism, the administration of dextrose after laparoscopic colon surgery results in a significant suppression of endogenous glucose production (an index of gluconeogenesis), with no protein-sparing capacity.⁶⁹ This implies enhanced whole-body

glucose uptake and greater utilization and oxidation of exogenous glucose. Insulin, growth hormones, and anabolic steroids have been shown to improve wound healing, directing aminoacids toward anabolic pathways to enhance lean tissue synthesis.

ANESTHETIC TECHNIQUES

General Anesthesia

After general anesthesia for fast track surgery, the patient should be able to walk out of the hospital with minimal side effects. Therefore, the choice of anesthetic agents should include fast-acting IV drugs and less soluble volatile anesthetics, along with adjuvants to minimize the side effects.

Propofol is the IV agent of choice for induction of fast track anesthesia.⁷⁰ For maintenance of anesthesia, highly soluble volatile anesthetic agents, such as desflurane and sevoflurane, offer advantages over propofol and isoflurane, in that they facilitate early recovery.^{71–73} Nitrous oxide (50–70%) remains a popular adjuvant during the maintenance period because of its anesthetic- and analgesic-sparing effects, low cost, and favorable pharmacokinetic profile;⁷⁴ however, it is not recommended in subjects at risk for PONV, nor is it suitable for laparoscopic surgery when the operating time is longer than 1 hour. Prolonged use of nitrous oxide causes bowel distention (the so-called gas effect) and predisposes to PONV. When general anesthesia is maintained with volatile anesthetic agents, there is an increased risk of PONV in the early postoperative period; accordingly, it is suggested that low-dose droperidol (0.625 mg) and dexamethasone (4–8 mg) should be used to provide effective antiemetic prophylaxis.⁷⁵ Titration of both IV and inhaled anesthetics using cerebral monitoring devices may also facilitate the fast track process,^{76–79} except in spontaneously breathing patients.⁸⁰

With regard to opioids, fentanyl remains a good choice, though infusion of the ultra-short-acting opioid remifentanyl (0.05–0.15 µg/kg/min) is an increasingly popular alternative for short and painful conditions. Whereas intraoperatively administered fentanyl can maintain some residual effect during the postoperative period, remifentanyl is rapidly metabolized; thus, one must remember that as soon as the remifentanyl infusion ends, the patient can be in serious pain. Long-acting opioids must therefore be administered in due time. The use of nonopioid analgesics (e.g., NSAIDs, [including COX-2 inhibitors], acetaminophen, alpha₂ agonists, glucocorticoids, ketamine, and local anesthetics in the wound) are recommended as part of a multimodal analgesic regimen aimed at reducing opioid-related side effects.^{81,82} Adjuvants such as beta blockers and lidocaine have had some success in reducing opioid use during and after laparoscopic surgery. These compounds represent an alternative to short-acting opioids in controlling for any associated acute autonomic responses.^{83–85}

Short- or intermediate-acting muscle relaxants are used for fast track surgery because they often do not need to be reversed. A novel agent, sugammadex (a cyclodextrin compound),⁸⁶ has been shown to provide faster reversal of nondepolarizing muscle relaxants without anticholinergic side effects,⁸⁷ thus facilitating earlier tracheal extubation and

reducing postoperative respiratory complications as a result of residual muscle paralysis.

In summary, short-acting anesthetic drugs and adjuvants minimize postoperative side effects and enhance the ability to fast track patients after both ambulatory and major inpatient surgical procedures. Not surprisingly, combining short-acting anesthetic techniques with an educational program has been reported to increase fast tracking significantly in ambulatory centers. Although a majority of adults can be fast-tracked after ambulatory surgery under general anesthesia, minimizing patient discomfort and anxiety is critically important for establishing a successful fast track surgery program for all types of elective surgery.

Regional Anesthesia

Regional anesthetic techniques (spinal, epidural, and peripheral nerve blocks) have several advantages over general anesthesia—including improved pulmonary function, decreased cardiovascular demand, a lower incidence of ileus, and good quality of analgesia at rest and on ambulation—both when used in place of GA and when used as adjuvants. The appropriate combination of a local anesthetic with an adjuvant will facilitate readiness for discharge. Consequently, epinephrine should not be added to spinal local anesthetics, because it might delay time to micturition; however, fentanyl in small doses does not interfere with bladder function.^{88,89} Faster recovery of sensory and motor function results when minidose lidocaine (10–30 mg), bupivacaine (3.5–7 mg), or ropivacaine (5–10 mg) spinal anesthetic techniques are combined with a potent opioid analgesic (e.g., fentanyl [10–25 µg] or sufentanil [5–10 µg]).^{90,91} However, postoperative side effects (e.g., pruritus, nausea) are increased when intrathecal opioids are used.

Thoracic epidural blockade is the most effective technique for postoperative analgesia. Whether in the form of a continuous infusion or of patient-controlled analgesia (PCA), epidural analgesia results in better static and dynamic pain relief than IV opioid-based PCA delivery systems.⁹² Epidural block with local anesthetics reduces the endocrine and metabolic responses to surgery, improves pulmonary outcome after major abdominal and thoracic operations (e.g., aortic surgery⁹³ and thoracoabdominal esophagectomy),⁹⁴ and facilitates the return of bowel function, while resulting in better preservation of perioperative nutritional profiles, higher health-related quality-of-life scores, and improved exercise capacity after colon surgery⁵⁹; however, it has not been found to affect the duration of hospitalization. Over the past 20 years, several randomized controlled studies and meta-analyses have been conducted to study the effect of spinal and epidural block on postoperative outcome. One large meta-analysis reported that morbidity and mortality were significantly lower with spinal and epidural analgesia than with general anesthesia and systemic opioid analgesia,⁹⁵ but these benefits could not be demonstrated in several subsequent randomized, controlled trials. However, these studies were not controlled for factors that might influence the stress response, including hypothermia, immunosuppression, hypoxemia, perioperative surgical and nursing care, infection, and the use of drains and tubes. One might therefore assume that the beneficial effects of regional anesthesia on

postoperative mortality and morbidity are most apparent when it is used as part of a multimodal therapeutic regimen in which all evidence-based therapeutic strategies have been put in place.

With regard to some biologic outcome measures, thoracic epidural analgesia with a local anesthetic and administration of opioids reduce ileus and lead to faster discharge after colonic surgery in patients enrolled in a fast track program (i.e., in patients being treated with multimodal techniques that include preoperative preparation, attenuation of the intraoperative stress response, multimodal analgesia, early oral feeding and mobilization, and early removal of drains and tubes).^{6,96} A role for epidural analgesia as part of a multimodal analgesia technique has also been suggested in the setting of fast track cardiac anesthesia,^{97–100} in which epidural local anesthetics have been associated with earlier tracheal extubation, decreased pulmonary complications and cardiac dysrhythmias, reduced postoperative pain and opioid analgesic requirements, shorter stays in the intensive care unit (ICU), and faster recovery of bowel and bladder function.^{101–103} However, with advances in MIS, the perioperative use of mu-receptor antagonists and other analgesia adjuvants, and the advent of fast track accelerated recovery programs in which all surgical, anesthetic, and nursing care elements are revised according to scientific evidence, the role of thoracic epidural technique in some types of surgery must be reconsidered.¹⁰⁴

Incisional Local Anesthesia

Infiltration of local anesthetics into the surgical wound is an effective analgesia technique for minor surgical procedures (e.g., hernia repair, anal surgery, and breast procedures). When possible, local infiltration should be performed before the surgical incision is made and should be a component of all balanced fast track anesthetic techniques.^{105,106} Better analgesia results when the infiltration of local anesthetics is supplemented with a peripheral nerve block (e.g., ileoinguinal block for inguinal hernia repair).¹⁰⁶ Compared with neuroaxial or general anesthetic techniques, local anesthetic infiltration techniques reduce the risk of postoperative urinary retention associated with anorectal surgery¹⁰⁷ and inguinal herniorrhaphy.^{108,109} The instillation of local anesthetics on the visceral peritoneum during laparoscopy has only weak and short-lasting analgesic effects.¹¹⁰

Continuous wound infusion with local anesthetics has been used for abdominal, gynecologic, and thoracic operations, and many studies have shown it to yield improved analgesia, greater patient satisfaction with pain management, reduced PONV, and shorter hospital stay.¹¹¹ Continuous infusion of bupivacaine at the median sternotomy incision site after cardiac surgery not only provides good postoperative pain relief but also allows patients to ambulate earlier, leading to a shorter hospital stay.^{112,113} A systematic review of randomized trials of the efficacy of continuous wound irrigation with local anesthetics for postoperative analgesia demonstrated good analgesia and opioid-sparing, with reduced side effects.¹¹¹ Nevertheless, the quality of analgesia can be highly variable even in a given patient or a given type of surgery, which highlights the difficulty of interpreting the results.

MAINTENANCE OF NORMOTHERMIA

During major surgery, body temperature falls by approximately 1° to 2°C as a result of loss of body heat and inhibition of the thermoregulatory response. Whereas a small drop in core temperature is not a cause for concern in fit and healthy persons, it can be detrimental in elderly, malnourished, or frail persons with cardiorespiratory and metabolic instability. Mild hypothermia elicits a stress response during the recovery period while the patient attempts to regain normothermia by means of shivering and vasoconstriction. It results in increased cardiovascular demands, elevated oxygen consumption, hypoxia, and impaired coagulation and leukocyte formation. Maintenance of intraoperative normothermia with the use of active and passive warming devices in conjunction with aggressive postoperative management of shivering and residual hypothermia decreases the incidence of wound infections, blood loss, myocardial ischemia, and protein breakdown.¹¹⁴

FLUID MANAGEMENT

Intraoperative fluid management strategy remains controversial, in that adverse outcomes may be associated with both inadequate and excessive fluid administration.^{115–117} Inadequate fluid administration can lead to a reduction in effective circulating volume, with diversion of blood towards the brain and heart and away from the gut, skin, and kidneys. Liberal (as opposed to restrictive) IV fluid administration improves gut perfusion and increases left ventricular stroke volume. In contrast, excessive IV fluid administration may result in adverse effects. Excess fluid in the intravascular compartment leads to increased venous pressure and pulmonary and peripheral edema that may compromise peripheral oxygenation. Two studies have suggested that excessive hydration can increase postoperative morbidity and lengthen the hospital stay after major abdominal surgery.^{118,119} In these studies, perioperative water and salt restriction reduced cardiopulmonary and tissue healing complications and prevented hyperchloremic metabolic acidosis after abdominal surgery. On the other hand, after laparoscopic cholecystectomy, large volumes of intraoperative fluid have been associated with reduced side effects (e.g., pulmonary dysfunction, dizziness, drowsiness, thirst, and PONV) and a shorter hospital stay.¹²⁰ Although aggressive crystalloid administration during colorectal surgery improves tissue oxygenation,¹¹⁷ it does not reduce the risk of surgical site infection (SSI).¹²¹

Perioperative fluid administration should take into account preoperative dehydration resulting from fasting and bowel preparation, replacement of blood loss and secretions, and maintenance hydration. The volume and composition of the fluid, together with the type of surgery performed and the patient's hemodynamic requirements, influence the duration and magnitude of intravascular volume expansion. Intraoperative esophageal Doppler monitoring can facilitate goal-directed fluid administration by targeting specific values for the cardiac index. Several studies have been conducted on different types of surgical procedures, and the outcomes have been positive (shorter length of hospital stay, lower incidence of admission to ICU, and fewer complications) when fluid administration was guided by a predetermined stroke volume and filling pressure.^{122,123} Therefore, strategies that avoid both hypovolemia and postoperative fluid overload are important in facilitating the fast track recovery process.

MINIMIZATION OF INCISION SIZE AND USE OF MIS

The size and orientation of the surgical incision are dictated primarily by the location and extent of the pathology, the need for exposure, the requirement for stoma placement (if applicable), the likelihood of further abdominal surgery, and the patient's body habitus. The incision should be as small as possible while allowing adequate exposure. Transverse incisions are used when possible by some fast track colorectal groups (though not by all). A meta-analysis found clinical outcomes after transverse or midline incisions to be similar overall.¹²⁴

Laparoscopic techniques are used when possible. In comparison with conventional open surgery, laparoscopic surgery is associated with better preservation of systemic immune function,^{125,126} less pulmonary compromise,¹²⁷ a lower incidence of ileus,¹²⁸ a shorter hospital stay, and earlier resumption of regular activities.^{129–134} In addition, the risk of SSI,¹³⁵ incisional hernia,^{136,137} and small-bowel obstruction¹³⁸ may be reduced with laparoscopic approaches.

In the setting of colorectal surgery, it is unclear at present whether the laparoscopic approach further improves on the short-term recovery benefits already seen with multimodal rehabilitation programs; benefits have been reported in some studies^{138,139} but not in others.^{140,141}

Postoperative Issues

PAIN MANAGEMENT

Pain remains the most common reason for delaying discharge after ambulatory surgery,¹⁴² while good analgesia accelerates restoration of function and improves recovery [*see 1:6 Postoperative Pain*].¹⁴³ Although there is no direct relation between analgesic techniques and postoperative morbidity and mortality,¹⁴⁴ optimal pain control, in combination with other interventions, remains a priority for the physician in the perioperative period. The pathophysiology of postoperative pain is characterized by a combination of nociceptive stimuli from the wound, inflammation and sensitization of peripheral somatic and visceral nerve terminals and central neurons, and inhibition of central descending control. It is therefore necessary to approach pain in a multidisciplinary fashion, whereby different treatment modalities complement each other with the aim of improving analgesia while minimizing the side effects associated with each treatment.

Opioids remain the most successful compounds for postoperative pain control, but they are associated with several important side effects (e.g., acute opioid tolerance, hypoventilation, sedation, ileus, nausea and vomiting, and urinary retention), any of which may delay hospital discharge. Accordingly, it is sensible to consider multimodal analgesia as the next step in providing optimal pain control. In this approach, the synergistic or additive effects of a variety of analgesics are exploited, allowing the individual doses to be reduced and thereby minimizing individual drug-related side effects. Intraoperative use of adjuvants such as ketamine, clonidine, dexmedetomidine, adenosine, gabapentine, dexamethasone, lidocaine, beta blockers, magnesium, and neostigmine has an opioid-sparing effect during the whole perioperative period.

The use of peripheral nerve blocks and conduction blockade for major and minor surgical procedures in combination with adjuvants provides excellent analgesia, though not always consistently. One reason for partial analgesic failures might be that too often, the analgesia regimen has not been optimized for a specific procedure. Accordingly, various procedure-specific analgesic regimens have been developed. On the basis of published evidence, the addition of either NSAIDs or regional analgesia and beta blockers to opioids enhances the quality of analgesia and exerts significant opioid-sparing effects.¹⁴⁵ At present, the evidence does not support adding acetaminophen to an opioid; however, the combination of acetaminophen with an NSAID provides better analgesia than either drug alone. More work is needed to verify whether the combination of several nonopioid analgesics could produce good analgesia with minimal side effects.⁸¹ In the meantime, the current strategy for postoperative analgesia involves a combination of regional and local anesthesia, MIS, and nonopioid pharmacologic interventions.

POSTOPERATIVE NAUSEA AND VOMITING

PONV continues to be a common complication of surgery, with an overall estimated incidence of 20 to 30%. PONV delays discharge from the postanesthesia care unit (PACU) and is the leading cause of unanticipated hospital admission in ambulatory surgical patients. Vomiting increases the risk of aspiration and has been associated with suture dehiscence. Nausea and vomiting remain the most common reasons for poor patient satisfaction during the postoperative period. In one study, a simplified risk factor chart was developed that identified four main risk factors for PONV: female sex, nonsmoking status, a history of PONV, and opioid use.¹⁴⁶ The incidence of PONV in patients with none, one, two, three, or all four of these risk factors was approximately 10%, 20%, 40%, 60%, and 80%, respectively. In a large study of 18,000 ambulatory patients, general anesthesia was associated with an 11-fold higher incidence of PONV than regional or local anesthesia was.¹⁴⁷ The risk of PONV has also been shown to increase with longer operating times.

Consensus guidelines for managing PONV recommend intraoperative pharmacologic strategies designed to compensate for baseline risk factors and modify the incidence of this complication. Currently available antiemetics may act at the cholinergic (muscarinic), dopaminergic (D₂), histaminergic (H₁), or serotonergic (5-HT₃) receptors. NK-1-receptor antagonists are also being investigated. A 2000 study introduced the concept of a multimodal approach to management of PONV in high-risk patients, utilizing total IV anesthesia (TIVA) with propofol and remifentanyl, ketorolac, no nitrous oxide, no neuromuscular blockade, IV hydration, ondansetron, droperidol, and dexamethasone.¹⁴⁸ This approach resulted in a 98% complete response rate (i.e., no PONV and no antiemetic rescue). A subsequent study comprising 5,000 patients employed a multifactorial design to evaluate three antiemetic interventions (ondansetron [4 mg], droperidol [1.25 mg], and dexamethasone [4 mg]) and three anesthetic interventions (TIVA with propofol, omission of nitrous oxide, and substitution of remifentanyl for fentanyl) for PONV prophylaxis.¹⁴⁹ Each antiemetic reduced the risk of PONV by approximately 26%. The efficacy of the interventions was dependent on the patient's baseline risk. The greatest

absolute risk reduction from the intervention was achieved in the patients at high risk for PONV. Consensus guidelines for management of PONV do not currently recommend prophylaxis for patients at low risk for PONV. For those at moderate risk, combination therapy with two antiemetic agents is recommended. For those at high risk, combination therapy with three antiemetic agents is recommended. In patients who experience PONV despite receiving prophylaxis, an antiemetic regimen acting at a different receptor should be used for rescue within the first 6 hours after surgery.¹⁵⁰ After 6 hours, PONV can be treated with any of the drugs used for prophylaxis except dexamethasone and scopolamine. Other useful adjuvants to standard antiemetic drugs include beta blockers, α_2 agonists, acupuncture, acupressure, and transcutaneous electrical nerve stimulation (TENS).^{151,152}

ILEUS

Postoperative ileus is defined as a temporary paralysis of the gut after major surgical procedures. It occurs as a consequence of sympathetic reflexes resulting from surgery and pain and of production of local and systemic inflammatory mediators. The effect on bowel motility can last up to 72 hours in the colon. Ileus causes discomfort and delays oral food intake, thereby prolonging recovery and the duration of hospitalization. The most effective technique for reducing ileus is continuous thoracic epidural administration of local anesthetics to block sympathetic visceral innervation and reestablish the balance between vagal and sympathetic neural influence on the gut. Other interventions, such as early feeding, prokinetics like metoclopramide and cisapride (currently unavailable because of a high incidence of cardiac dysrhythmias), prophylactic nasogastric intubation, have only minor effects on the occurrence of ileus. In the past few years, there has been some interest in the mu-receptor antagonist alvimopan, which may reduce the effect of opioids on the gut mucosa, favor the restoration of bowel function, and accelerate hospital discharge.^{153–155}

Within multimodal programs in GI surgery, the combination of epidural analgesia using diluted concentrations of local anesthetics and minimal amounts of opioids, aggressive PONV prophylaxis, and early oral feeding and mobilization has been found to shorten the duration of ileus.⁹⁶ There is also evidence that reduced perioperative sodium administration and avoidance of fluid excess¹⁵³ are associated with earlier return of bowel function after abdominal surgery and a shorter hospital stay.¹⁵⁶ IV infusion of lidocaine during surgery and the first 24 postoperative hours has been shown to minimize ileus and facilitate dietary intake.^{85,157}

POSTOPERATIVE FEEDING

GI motility is predictably decreased after major abdominal surgery, with colonic motility requiring 3 to 5 days to recover. On the assumption that bowel rest shortens the duration of ileus and protects anastomoses, patients have traditionally been kept fasting until peristalsis has returned throughout the entire GI tract, as evidenced by passage of flatus or stool¹⁵⁸; a step-wise progression of oral intake is then allowed, resulting in a planned minimum perioperative starvation period of several days. Yet after abdominal surgery, interruption of oral intake is actually neither necessary nor beneficial in most

patients.¹⁰ After colorectal surgery, feeding before complete return of peristalsis is tolerated by most patients.¹⁵⁹ Meta-analysis of randomized trials comparing early enteral or oral feeding with fasting after various types of elective GI surgery found no obvious advantages to keeping patients on NPO status, with several studies suggesting that early feeding offered benefits, such as decreased overall infectious complications and reduced length of stay. Although the risk of vomiting is somewhat higher with early feeding, the risk of anastomotic dehiscence is not increased.¹⁶⁰ One caveat is that most studies of early oral feeding involve patients undergoing colorectal resection, which means that the results may not be applicable to patients with upper GI anastomoses.

In fast track surgery, the protocol should be tailored in accordance with the procedure being done and by the patient's tolerance (e.g., as evidenced by PONV and abdominal distention). After most types of abdominal surgery, patients are encouraged to take liquids on the night following the operation, with light solids given on the morning of postoperative day 1 and a normal diet initiated on postoperative day 2. Protein-rich drinks are given between meals. This approach allows patients to resume recommended energy and protein intake in just a few days and preserves lean body mass, particularly when combined with thoracic epidural analgesia and early mobilization.¹⁶¹ Setting specific daily goals that are understood by the patients and formulating protocol-based orders for the nursing staff are important for achieving adequate oral intake of calories and protein, given that simply starting clear fluids on postoperative day 1 without a structured, written plan does not prevent negative nitrogen balance.¹⁶²

In patients for whom early oral feeding is not possible (e.g., those who have undergone major head and neck surgery, esophageal or gastric anastomoses, or pancreaticoduodenectomy), especially in those who were undernourished preoperatively, enteral tube feeding should be considered. This is done via a tube placed distal to the anastomosis at the time of surgery; either a nasojejunal tube or a feeding jejunostomy may be employed. Enteral feedings are started at a low rate (10–20 mL/hr) within 24 hours after the procedure and are slowly increased over the next few days as the patient's tolerance permits.¹⁰

In undernourished patients, oral nutritional supplements are continued for 10 weeks after discharge; this approach results in less weight loss, faster weight regain, better preservation of muscle mass and grip strength, and improved quality of life.¹⁶³

MOBILIZATION

Postoperative bed rest should be discouraged. In addition to impairing pulmonary function and predisposing to thrombotic complications,¹⁶⁴ bed rest reduces exercise capacity in a linear fashion¹⁶⁵ and decreases muscle mass¹⁶⁶ and strength¹⁶⁷ (a result that may be related to the development of postoperative fatigue¹⁶⁸). Although the association of early postoperative mobilization with faster recovery and lower pulmonary and thrombotic complications has been acknowledged since the 1940s,¹⁶⁹ modern surgical patients actually spend very little time out of bed in conventional care plans. For example, patients in the control arm of a trial comparing fast track care with conventional care after

colorectal resection spent a median of 8 minutes out of bed on postoperative day 1, despite having been given thoracic epidural analgesia.¹⁷⁰ In an observational study of patients who had undergone upper abdominal surgery, the total median upright mobilization time was only 34 minutes on postoperative day 4, and mobilization time predicted length of stay.¹⁷¹

Structured postoperative mobilization is an important component of fast track surgery protocols, and patients should be given explicit written instructions preoperatively that outline the benefits of early mobilization. These instructions include specific goals for each day, which are also included in the postoperative nursing orders. The nursing culture and the ward environment should encourage and enable patient independence. Adequate pain control using thoracic epidural analgesia with local anesthetics facilitates effective early mobilization.⁴ Asking patients to maintain a diary of the time spent out of bed and walking or suggesting that they use a pedometer to self-monitor their ambulation may help with compliance. Placing a wall chart at the bedside that lists mobilization and diet goals for each day is also helpful.¹⁷²

Because patients in fast track protocols spend significantly more time out of bed in the first postoperative week, the decrease in voluntary muscle strength traditionally seen after major abdominal surgery is prevented.^{173,174} The importance of early mobilization may be independent of other elements of the protocol, in that compliance with “out-of-bed” day 0 has been found to be a significant predictor of hospital stay, even after other fast track elements, patient characteristics, presence of complications, and additional factors have been adjusted for.¹⁷⁵

USE OF DRAINS AND CATHETERS

Routine use of nasogastric tubes and abdominal drains after abdominal surgery is not supported by the evidence; instead, selective use, based on clinical circumstances, is indicated. Drains and catheters impede independent ambulation,¹⁷¹ can be painful, and may pose a psychological barrier to recovery.⁷ A meta-analysis of randomized trials concluded that routine nasogastric decompression after abdominal surgery does not hasten recovery from ileus, increases pulmonary complications after upper abdominal surgery, is uncomfortable, and should be abandoned.¹⁷⁶ With respect to foregut surgery, anastomotic leaks were not increased in two randomized trials of routine versus selective nasogastric decompression after partial or total gastrectomy.^{177,178}

Similarly, reviews of randomized trials do not support the use of routine prophylactic drainage for colorectal anastomoses,¹⁷⁹ thyroid surgery,¹⁸⁰ cholecystectomy,^{181,182} uncomplicated liver resection,¹⁸³ or pancreatic resection.¹⁸⁴ Routine drainage is associated with an increased SSI rate and a longer hospital stay after laparoscopic cholecystectomy,¹⁸¹ an increased hospital stay after thyroid surgery,¹⁸⁰ and increased SSI and chest infection rates after open cholecystectomy¹⁸²; it does not lower the incidence or improve the diagnosis of anastomotic leaks after colon surgery,¹⁸¹ nor does it decrease abdominal sepsis after pancreatic resection.¹⁸⁴

It is common practice to catheterize the bladder just before major operations to monitor postoperative urine output and prevent the development of postoperative urinary retention. Because epidural local anesthetics block the transmission

of afferent and efferent nervous impulses from and to the bladder, it is customary to keep the bladder catheterized for as long as epidural analgesia is in force. However, urinary catheters may cause discomfort and impede mobilization. In addition, the risk of urinary infection increases with the duration of catheterization.¹⁸⁵ Urinary infections prolong the hospital stay, are expensive to treat, and cause unpleasant symptoms. The incidence of urinary retention after epidural analgesia has been reported to be between 18 and 23%.¹⁸⁶ In one study, as part of an accelerated recovery program, bladder catheterization was discontinued 24 hours after colon surgery in 102 patients receiving continuous postoperative epidural analgesia; the incidence of bladder recatheterization was low (only 9%).¹⁸⁷ Accordingly, current practice, unless it is contraindicated by the type of surgery or by the need for ongoing monitoring of urinary volumes, is to remove urinary catheters 24 to 36 hours after the surgical procedure.

DISCHARGE CRITERIA

Patients can be discharged home when their oral intake is adequate, their pain is well controlled with oral analgesics, they are voiding without difficulty, they are passing flatus or stool, they ambulating independently or at baseline levels, they feel ready for discharge, and they are able to care for themselves at home.⁴ Yet even within an enhanced colorectal recovery program, only 30% of patients are actually discharged on the day of functional recovery; thus, it is clear that length of stay is not determined solely by medical factors but is also greatly influenced by social and cultural factors.¹⁷⁵

POSTDISCHARGE FOLLOW-UP

Because of the earlier hospital discharge with fast track programs, it is important that patients be able to contact a team member easily should problems like fever, wound redness or discharge, PONV, or worsening abdominal pain arise. A follow-up telephone call should routinely be made 24 to 36 hours after patients go home. Patients should be seen between postoperative day 7 and 10 so that the wound can be checked and their overall status assessed, then seen again at 1 month after the operation. Depending on the planned discharge day, the risk of readmission after fast track colon surgery ranges from 10 to 20%.

Studies of the duration of convalescence after abdominal surgery report great discrepancies in the time away from regular activities; these discrepancies are partly attributable to variations in how patients are instructed.¹⁸⁸ Very little information is available about the recovery period after surgery, and a standardized approach to measurement of surgical recovery is lacking. After discharge, patients are given specific written instructions outlining the expected recovery course. They are encouraged to continue the exercise program begun preoperatively, with a goal of 30 to 60 minutes of exercise per day. Undernourished patients continue to receive oral nutritional supplements. No specific restrictions are placed on the resumption of specific activities.

OTHER COMPONENTS

The preceding discussion outlines many of the more common components of multimodal perioperative rehabilitation. Specific programs may include a variety of other interventions, such as the administration of probiotics, the avoidance of standard mechanical bowel preparation,¹⁸⁹ and the use of prokinetics and laxatives.^{4,6}

Implementation of Fast Track Surgery Program

ORGANIZATIONAL ISSUES

Implementation of a multimodal rehabilitation requires substantial resources and effort. Success depends on the ability of the leader to interface with numerous stakeholders over time in order to reach a multidisciplinary consensus. Several aspects of perioperative care (e.g., the use of drains, dietary and activity restrictions, and fluid management) that may have been passed down through generations of training are abandoned or significantly revised in fast track protocols. In addition, the differences in patient preparation and education necessitate revision of information given to patients

and expansion of the role played by the surgeon or perioperative caregiver in the preoperative phase. Certain surgical techniques (e.g., the use of transverse incisions or MIS) may require surgeons to hone new skills; similarly, the significant role of thoracic epidural analgesia and pharmacologic modulation of the stress response to surgery may require anesthesiologists to play a dramatically expanded role. Early ambulation, goal-driven protocols for oral nutritional supplementation, the presence of thoracic epidural analgesia, and early withdrawal of urinary catheters significantly change the way nursing care is provided on the postoperative ward. Although guidance from published studies of successful fast track programs is available, especially in the colorectal

Table 1 Organization of Multimodal Perioperative Care Plan for Specific Procedure or Group of Procedures¹

Step	Personnel Involved	Specific Task	Time Line	Comments
1. Develop protocol	Everyone who interfaces with surgical patient: surgery, anesthesia, nursing (preop, postop, postdischarge), nutrition, psychology, physiotherapy, pharmacy	Write pathway	Meetings for 1–2 hr/wk for 1–2 mo	Requires committed leader and team members with ability to reach consensus; requires significant time and energy commitment
2. Outline specifics of preoperative preparation	Surgeon Consulting internist Nutrition Physiotherapy	Evaluate need for routine tests; standardize strategy for prevention of complications; optimize nutrition and fitness	~25 hr	Emphasis on optimization of cardiopulmonary disease, glycemic control, prevention of infectious and thrombotic complications, smoking cessation, alcohol, weight loss
3. Develop anesthesia and analgesia programs	Anesthesiology/pain service Surgery Nursing Pharmacy	Optimize regional techniques to reduce stress response and optimize pain management	1–2 mo	May require special training for thoracic epidural analgesia and other neural blocks; requires postoperative protocol for nursing unit
4. Minimize stress of surgery	Anesthesiology/pain service Surgery Nursing	Optimize anesthetic technique; minimize incision size; prevent hypothermia		Give short-acting opioids or short-acting muscle relaxants; use local anesthetics in thoracic epidural; preferably use vasopressor for hypotension versus overhydration
5. Adjust postoperative care according to evidence	Surgery Nursing Pain service	Modify routine use of nasogastric tubes, drains, and bladder catheters; protocolize feeding and ambulation with specific daily goals		Create standard postoperative orders
6. Develop postoperative nursing care programs	Nursing Physiotherapy Nutrition	Enforce feeding, ambulation and sleeping protocols; determine hospital discharge criteria		Staff may benefit from visiting an established program
7. Determine methods for follow-up	Surgeon Nursing Surgical assistant Pharmacy	Arrange telephone follow-up and office visit		Standardize discharge orders and instructions, including nutrition and physical activity; develop protocols for response to nausea, vomiting, pain, fever, wound problems
8. Develop patient information program	All team members, possibly headed by patient educator	Develop standard oral, written, and electronic material to educate patient before operation		
9. Document results and tabulate problems and patient satisfaction; revise and improve	All team members, perhaps headed by data manager	Choose outcome measures and method of follow-up		Identify methods for reassessment and pathway failure

surgery literature, there are no off-the-shelf protocols, and local differences in expertise, experience, and resources will inevitably shape the development of the protocol for each individual center. To further complicate implementation, each surgical procedure or family of procedures requires an individual protocol with specialized input from a team that is experienced in caring for this subset of patients. Even after the protocol is implemented, compliance remains an important issue that necessitates ongoing monitoring and adjustment, particularly to ensure compliance with the postoperative components.¹⁷⁵ Creating the protocol is necessary for success but not sufficient to ensure it; even within a fast track program, patients cared for by surgeons who are new adopters have longer hospital stays than those cared for by surgeons experienced with the protocol.¹⁷²

The implementation process has been well described¹ and includes the following major steps [see Table 1]:

1. Assemble the relevant stakeholders (the multidisciplinary team).
2. Examine the evidence for components of perioperative care.
3. Interpret the evidence in the light of local experience, patient population, resources, and so forth.

4. Write, circulate, and revise the protocol.
5. Implement the plan.
6. Measure the outcomes with timely feedback.
7. Revise the protocol in the light of the outcomes.

Once the protocol is introduced, there is an adjustment and learning period for the medical and nursing personnel, which is estimated to last about 1 year.¹⁹⁰

Examples of multimodal perioperative care plans for inpatient and outpatient surgical procedures are available [see Table 2, Table 3, Table 4, and Table 5].

CONTRAINDICATIONS

Whether fast track surgery is applicable to a wide variety of patients and procedures has been questioned. Fast track protocols seem to be feasible for most patients undergoing elective colon surgery, as demonstrated by a report from 24 German centers of various sizes and affiliations that voluntarily adopted the same fast track protocol.¹⁹¹ Compliance and outcomes were prospectively documented in more than 1,000 patients with a median age of 66 years. More than 30% of the patients had significant comorbid disease (American Society of Anesthesiologists [ASA] class 3 or 4). Compliance with the protocol was high, with more than 85% of the

Table 2 Sample Multimodal Perioperative Care Plan for Elective Colorectal Resection

Preoperative assessment and optimization Evaluation of medication compliance and control of risk factors: hypertension, diabetes, COPD, smoking, alcohol, asthma, CAD, malnutrition, anemia Psychological preparation for surgery and postoperative recovery: explanation of preoperative bowel preparation, importance of generous clear fluid intake up to 2 hr before surgery, intraoperative and postoperative trajectory and hospital stay (2–4 days for nonrectal surgery, > 4 days for rectal surgery), immediate postoperative mobilization, early oral intake, presence of routine bladder catheter for 24 hr Physical preparation with exercises at home: anaerobic and resistance 1–2 hr/day, gradual increase from 50% to 80% of maximum capacity, breathing exercises Surgical considerations: laparoscopic or laparotomy, risk of SSI, drains, bleeding risk, strategies for blood loss reduction. Familiarization with epidural analgesia: occasional numbness in lower extremities, short spells of hypotension, pain assessment at rest and on coughing and walking, care of the epidural catheter, explanation of possible risks (hematoma and paralysis, pain and abscess) Nutritional preparation: oral nutritional supplements for patients with diminished oral intake or mild undernutrition Intraoperative management <i>Anesthetic management</i> Allay anxiety with midazolam and good hydration. Insert epidural catheter at appropriate intervertebral level (T7–8 for right, transverse, and left hemicolectomy; T9–10 for sigmoid and rectal resection). Use local anesthetics, and test epidural blockade for bilateral spread. Infuse local anesthetics during surgery. Give minimal amount of IV opioids throughout surgery. Administer prophylactic antiemetics, antibiotics, and DVT prophylaxis. Avoid overhydration. Avoid blood replacement in cancer resection. Maintain normothermia. Use BIS to guide anesthesia titration. Avoid neostigmine to reverse muscle relaxants. <i>Surgical care</i> Minimize incision size, and use MIS if possible. Achieve accurate hemostasis and thorough removal of debris. Check integrity of anastomosis. Do not routinely place nasogastric and abdominal drains. Postoperative strategy <i>PACU</i> Discharge criteria: patient alert, cooperative, pain free, warm, normotensive, able to lift legs; urine output > 0.5 mL/kg <i>Surgical ward</i> Day of surgery (0–24 hr): Mobilize patient for 2 hr in chair and 2 hr walking, starting 6 hours after operation, and increase by 50% daily. Have patient drink fluids, including nutritional supplements. Hold oral intake if abdomen distended. Place NG tube for persistent PONV (repeated in subsequent days). Confirm working epidural block with VAS for pain at rest, cough, and mobilization. Check skin site (repeated in subsequent days). Give oral acetaminophen, 1 g q. 4 hr, and NSAID (repeated in subsequent days). Postoperative day 1 (24–48 hr): Remove urinary catheter in the morning. Mobilize patient for at least 6 hr. Institute light oral diet, including nutritional supplement. Postoperative day 2 and later (> 48 hr): Mobilize patient fully. Institute regular diet. Transition from epidural to oral medication (oxycodone + oxycodone + acetaminophen + NSAIDs) if epidural stop test is successful (repeated in subsequent days if epidural stop test is not successful). Enforce criteria for discharge: passing gas or stool, no fever, minimal pain, walking unattended, eating. If five criteria are fulfilled, patient can go home. <i>Post discharge</i> Instructions while recovering at home or on chemotherapy/radiotherapy: normal diet (± supplements), exercise every day for 1–2 hr, no opioids for pain relief, psychological support Clinic visit on postoperative day 14: check wound and overall recovery; discuss pathology and further treatment; plan further follow-up	
--	--

BIS = bispectral index monitor; CAD = coronary artery disease; COPD = chronic obstructive pulmonary disease; DVT = deep vein thrombosis; MIS = minimally invasive surgery; NG = nasogastric; NSAID = nonsteroidal antiinflammatory drug; PONV = postoperative nausea and vomiting; SSI = surgical site infection; VAS = visual analog scale.

Table 3 Sample Multimodal Perioperative Care Plan for Ambulatory Laparoscopic Cholecystectomy

Preoperative assessment and optimization

Evaluation of medication compliance and control of risk factors: hypertension, diabetes, COPD, smoking, alcohol, asthma, CAD, malnutrition, anemia
Psychological preparation for surgery and postoperative recovery: explanation of perioperative pathway, postoperative out-of-hospital self-care, expectations about duration of recovery period
Day of surgery: drink clear fluids containing carbohydrate up to 2 hr before operation
Preinduction: give acetaminophen 1 gm and NSAID. Provide DVT prophylaxis.

Intraoperative management

Anesthetic management

Induce with propofol, give short-acting opiates for analgesia (e.g., fentanyl), consider adjuvants for analgesia (beta blockers [propranolol, esmolol] or lidocaine), administer rocuronium or desflurane.
Prevent PONV with dexamethasone, ondansetron, or droperidol.
Give normal saline, 2 L IV, over intraoperative and postoperative time.
Keep patient warm.

Surgical care

Provide incisional anesthesia with local anesthetic at beginning and end of case. Keep abdominal insufflation pressure as low as possible (12 mm Hg or less). Maximize use of small (5 mm) trocars.

Postoperative strategy

PACU

Provide analgesia with strong short-acting opioid (e.g., fentanyl). Manage PONV with ondansetron. Encourage postoperative oral fluid intake as soon as possible; do not wait for voiding to discharge from PACU.

> 6 hr after operation²⁰⁵

Provide nonopioid analgesia with NSAIDs (e.g., ketorolac, naproxen, COX-2 inhibitor) and acetaminophen. Add oxycodone, 5–10 mg q. 4 hr, if pain persists.

Post discharge

Provide written instructions for postdischarge care; no specific activity limitations need be placed. Schedule follow-up visit at 2 wk after surgery.

CAD = coronary artery disease; COPD = chronic obstructive pulmonary disease; DVT = deep-vein thrombosis; NSAID = nonsteroidal antiinflammatory drug; PACU = postanesthesia care unit; PONV = postoperative nausea and vomiting;

patients undergoing epidural analgesia, oral nutrition, and mobilization on the day of the operation. The median length of stay was 8 days, representing a 40% decrease from conventional German data. Readmissions occurred in 4% of cases. A 2001 study enrolled 60 consecutive patients undergoing elective laparotomy and intestinal surgery over a 6-week period, including many reoperative and complex pelvic cases; only two of the 60 patients had to be excluded from the fast track protocol on the basis of operative findings.¹⁹² Fast track colorectal surgery has been successfully performed in older patients,¹⁹³ patients with significant comorbidities (ASA class 3 or 4),^{192,194,195} and patients requiring complex operations.¹⁹⁵ Whether these results are applicable to more complex procedures in general is not known. In a study of fast track Ivor-Lewis esophagectomy, 75% of patients older than 70 years failed the protocol.¹⁹⁶

Readmission is a concern after early discharge from hospital. The rate at which readmission occurs is related to the planned day of hospital discharge, with readmission rates after colon surgery decreasing from 20% to 11% as planned hospital stays increase from 2 days to 3. The difference is mainly attributable to a reduction in readmissions for “social reasons” or observation; no significant differences in complications have been reported.¹⁹⁷ A systematic review of fast track studies in colon surgery found no overall increase in readmission rates over those seen with conventional care.⁶

RESULTS

There remains significant variability in perioperative care among individual surgeons, institutions, and geographic areas, and overall adherence with evidence-based recommendations and guidelines is still suboptimal.⁸ Consequently, it is likely that creation of any standard perioperative care proto-

col (also referred to as a critical pathway or clinical pathway) that multiple surgeons are willing to buy into may improve efficiency and outcomes simply by removing variability and improving compliance with evidence-based care. This phenomenon has been demonstrated not only for colon surgery¹⁹⁸ but also for more complex procedures such as pancreaticoduodenectomy¹⁹⁹ and aortic surgery.²⁰⁰ By themselves, however, pathways often are not effective in decreasing the length of stay.²⁰¹

Fast track surgery represents an extension of the critical pathway that integrates new modalities in anesthesia and nutrition, enforces early mobilization and feeding, and emphasizes reduction of the surgical stress response. It is hoped that this approach will not only improve efficiency by shortening the hospital stay and reducing variability, as any standardized protocol might, but also decrease the physiologic impact of major surgery, thereby reducing organ dysfunction and shortening the recovery time. Experience with fast track programs is accumulating in a number of different areas. Most reports are single-center studies focusing on colorectal surgery. A systematic review of three randomized trials and three additional prospective studies of enhanced recovery programs for colon surgery found that fast track protocols were associated with decreased ileus, duration of hospitalization, and morbidity, without any significant increase in the readmission rate.⁶ Fewer results are available for other types of abdominal surgery. Preliminary reports, however, suggest that it is possible to implement fast track protocols even for debilitated patients undergoing complex procedures. Some studies have reported dramatically low lengths of stay (e.g., a 3-day median length of stay after open aortic aneurysm repair,²⁰² a 2-day median length of stay after colon surgery,⁹⁶ and an 88% discharge rate on postoperative day 1 after laparoscopic donor nephrectomy²⁰³). Even if these results are not widely applicable, they might well stimulate us

Table 4 Sample Multimodal Perioperative Care Plan for Esophageal Resection²⁰⁶⁻²⁰⁸

Preoperative assessment and optimization

Initial evaluation of medication compliance and control of risk factors: hypertension, diabetes, COPD, smoking, alcohol, asthma, CAD, anemia

Psychological preparation for surgery and postoperative recovery: explanation of pathway, diet and mobilization plan, presence of drains, expectations for length of hospital stay (7–8 days) and postdischarge recovery

Physical preparation with exercises at home: anaerobic and resistance 1–2 hr/day, gradual increase from 50% to 80% of maximum capacity, breathing exercises

Surgical considerations: operative approach individualized on basis of tumor characteristics and location, patient comorbidity, previous surgery

Familiarization with epidural analgesia: occasional numbness in lower extremities, short spells of hypotension, pain assessment at rest and on coughing, walking, care of epidural catheter

Nutritional preparation: oral nutritional supplements for patients with diminished oral intake or mild undernutrition; formal nutritional assessment if malnutrition is more severe

Intraoperative management

Anesthetic management

Insert thoracic epidural catheter. Use local anesthetics, and test epidural blockade for bilateral spread. Infuse local anesthetics during surgery. Provide antibiotics and DVT prophylaxis. Give prophylactic antiemetics. Restrict fluids. Avoid blood transfusion. Maintain normothermia. Perform early extubation (preferably in operating room).

Surgical care

Minimize blood loss. Place feeding jejunostomy. Routinely place NG tube and chest tubes.

Postoperative strategy

Day of surgery (0–24 hr)

Admit to ICU or other unit with continuous monitoring of heart rate and pulse oximetry. Apply strict aspiration precautions; place head of bed at 30°, and place NG tube to suction. Restrict fluids postoperatively as dictated by hemodynamics (~1–1.5 mL/kg/hr crystalloid and 20–30 mL/hr urine output if renal function is normal). Place chest tube to suction. Have patient sitting in chair on evening of surgery if possible and ambulating in hall on morning after surgery. Perform incentive spirometry. Monitor chest tube and urinary output q. 4 hr. Obtain hemoglobin level q. 6 hr three times; measure electrolyte concentrations in morning.

Surgical ward

Postoperative day 1: Have patient ambulate 3–4 times daily; obtain physiotherapy consult. Perform incentive spirometry (repeated in subsequent days). Apply strict aspiration precautions; place head of bed at 30°; place NG tube to suction (repeated in subsequent days). Order complete blood count and electrolyte levels in morning (repeated in subsequent days). Obtain chest x-ray (repeated three times in subsequent days). Confirm working epidural block with VAS for pain at rest, cough, and mobilization; check skin site (repeated in subsequent days). Supply jejunal feedings at full concentration, starting at 20 mL/hr.

Postoperative day 2: Increase rate of jejunal feedings by 10 mL/4 hr until achieving target rate is achieved. Request nutritional therapy consult. Remove anterior chest tube. Ambulate a minimum of four times daily until discharge.

Remove bladder catheter unless urinary output is poor.

Postoperative day 3: Remove NG tube if abdomen is not distended and gastric conduit is not dilated on chest x-ray.

Remove last chest tube if drainage < 450 mL/day (reassess in subsequent days if drainage is higher). Transition from epidural to oral/J-tube analgesics (oxycontin + oxycodone + acetaminophen + NSAID) if epidural stop test is successful (repeated in subsequent days if epidural stop test is not successful).

Postoperative day 4 or 5: Transition from epidural to oral/J-tube analgesics (oxycontin + oxycodone + acetaminophen + NSAID) if epidural stop test is successful (repeated in subsequent days if epidural stop test is not successful). Perform sodium amidotrizoate–meglumine amidotrizoate swallow. If there is no leak, advance to full liquid diet with oral supplements. Continue jejunal feedings. Continue aspiration precautions: avoid eating if drowsy, and avoid recumbency within 3 hr of eating.

Postoperative day 5 or 6: Advance to soft diet. If patient is undernourished, start compressing jejunal feedings by increasing rate and turning off for 4 hr/day. Arrange for home nighttime feedings (7 pm to 7 am). Remove central line. Continue physiotherapy and aspiration precautions. Obtain nutritional education from dietitian.

Postoperative day 7: Discharge home on soft diet with aspiration precautions ± nighttime jejunal feedings.

Post discharge

Instructions while recovering at home and/or on chemotherapy/radiotherapy: eating normal diet (± supplements), exercise every day for 1–2 hr, no opioids for pain relief, psychological support

Clinic visit on postoperative day 14 to check wound and overall recovery, discuss pathology and further treatment, and plan further follow-up

CAD = coronary artery disease; COPD = chronic obstructive pulmonary disease; DVT = deep-vein thrombosis; ICU = intensive care unit; NG = nasogastric; NSAID = nonsteroidal antiinflammatory drug.

to question our assumptions about what keeps patients in the hospital after surgery.

More research is required to understand which of the multiple individual components of fast track surgery have the greatest impact.⁶ In addition, it remains unclear whether certain patients are more likely than others to benefit from fast track protocols. Several elements of this approach seem relatively consistent among fast track centers, at least with respect to colorectal surgery (e.g., thoracic epidural analgesia and the philosophy of encouraging early oral feeding and ambulation), whereas several others are more variable (e.g.,

use of probiotics, specific feeding protocols, preoperative carbohydrate administration, bowel preparation, and specific anesthesia protocols). Length of hospital stay is the most common outcome measure used, but this measure can be confounded by nonphysiologic issues: even within fast track programs, only a minority of patients are discharged on the day of functional recovery.²⁰⁴ Yet little research has been undertaken to achieve a better description of the recovery process, and there is no currently accepted outcome measure to define the length of clinical recovery. More research is also needed in the area of implementation.

Table 5 Sample Multimodal Perioperative Care Plan for Laparoscopic Foregut Surgery²⁰⁹

Preoperative assessment and optimization

Initial evaluation of medication compliance and control of risk factors: hypertension, diabetes, COPD, smoking, alcohol, asthma, CAD, anemia

Psychological preparation for surgery and postoperative recovery: explanation of pathway, diet and mobilization plan, expectations for length of hospital stay (1–2 days) and postdischarge recovery

Nutritional preparation: oral nutritional supplements for patients with diminished oral intake or weight loss

Intraoperative management

Anesthetic management

Address aspiration risk. Give short-acting opioids. Use TIVA with propofol to minimize PONV. Provide good muscle relaxation to facilitate surgical repair. Give prophylactic antiemetics to prevent postoperative retching (dexamethasone, 8 mg; droperidol, 0.625 mg; ondansetron, 4 mg). Provide DVT prophylaxis. Initiate active warming.

Surgical care

Use small trocars. Administer preincisional and postoperative local anesthesia. Avoid lithotomy position (use split table and bean bag). Apply pneumatic compression stockings. Do not routinely place Foley catheter or NG tube.

Give sips of water immediately after operation and fluids the morning after surgery. Request nutritional consult for education on posthospital surgery diet on postoperative day 1.

Have patient ambulate the night of the operation.

No routine postoperative investigations are required. Take stepwise approach to analgesia: start with NSAIDs and acetaminophen, avoid opiates if possible, and do not use PCA. Assess for discharge criteria after lunch on postoperative day 1 (fluids tolerated, no fever, pain controlled with oral analgesia).

CAD = coronary artery disease; COPD = chronic obstructive pulmonary disease; DVT = deep-vein thrombosis; NG = nasogastric; NSAID = nonsteroidal anti-inflammatory drug; PCA = patient-controlled analgesia; PONV = postoperative nausea and vomiting; TIVA = total intravenous anesthesia.

Acknowledgment

Portions of this chapter are based on a previous chapter "Fast Track Surgery" by Henrik Kehlet, MD, PhD, FACS (Hon) and Douglas W. Wilmore, MD, FACS. The authors wish to thank Drs. Kehlet and Wilmore.

10 FAST TRACK SURGERY

Henrik Kehlet, M.D., Ph.D., F.A.C.S. (Hon.), and Douglas W. Wilmore, M.D., F.A.C.S.

Over the past several decades, surgery has undergone revolutionary changes that are leading to improved treatments (involving lower risk and better outcome) for an increasing number of diseases. These salutary developments are the result of more advanced anesthetic techniques, new methods of reducing the perioperative stress response, wider application of minimally invasive techniques, improved understanding of perioperative pathophysiology, and more sophisticated approaches to the prevention of postoperative organ dysfunction. Currently, many operations that once necessitated hospitalization can readily be performed in the outpatient setting; in addition, many major procedures are now associated with a significantly reduced duration of hospitalization and a shorter convalescence.

Although these anesthetic and surgical developments are the result of basic scientific and clinical research, they have also been influenced by governmental and managed care policies aimed at encouraging more cost-effective treatments. Such extraclinical influences, coupled with new clinical developments, have resulted in novel approaches designed to enhance the cost-effectiveness of health care, such as so-called fast track surgery, critical pathways, and various types of clinical guidelines. To understand the true potential value of such approaches, it is essential to recognize that their aim is not merely to ensure that fewer health care dollars are spent but, more important, to ensure that better and more efficient health care is delivered. Although these novel approaches may reduce cost, their primary purpose is to improve surgical management by reducing complications and providing better outcomes. In what follows, we outline the basic concept, primary components, and current results of fast track surgery, which is a comprehensive approach to the elective surgical patient that is designed to accelerate recovery, reduce morbidity, and shorten convalescence.

Basic Concept

Fast track surgery involves a coordinated effort to combine (1) preoperative patient education; (2) newer anesthetic, analgesic, and surgical techniques whose aim is to reduce surgical stress responses, pain, and discomfort; and (3) aggressive postoperative rehabilitation, including early enteral nutrition and ambulation. It also includes an up-to-date approach to general principles of postoperative care (e.g., use of tubes, drains, and catheters; monitoring; and general rehabilitation) that takes into account the revisions to traditional practice mandated by current scientific findings. It is believed that by these means, fast track surgery can shorten the time required for full recovery, reduce the need for hospitalization and convalescence, and lower the incidence of generalized morbidity related to pulmonary, cardiac, thromboembolic, and infectious complications.¹⁻³

For an accelerated recovery program of this type to succeed, proper organization is essential. In general terms, fast track

surgery must be based on a process of multidisciplinary collaboration that embraces not only the surgeon, the anesthesiologist, the physiotherapist, and the surgical nurse but also the patient. More specifically, fast track surgery depends on the inclusion and integration of a number of key constituent elements (see below).

Constituent Elements

EDUCATION OF THE PATIENT

To obtain the full advantages of a fast track surgical program, it is essential to provide patients with information about their perioperative care in advance of the procedure. Such educational efforts often serve to reduce patients' level of anxiety and need for pain relief, thereby providing a rational basis for collaboration with health care personnel, a process that is crucial for enhancing postoperative rehabilitation.¹⁻³ Patients can supplement the information they receive directly from health care providers by accessing reference sources such as www.facs.org/public_info/operation/aboutbroch.html, a collection of electronic brochures on specific clinical procedures that is provided by the American College of Surgeons.

OPTIMIZATION OF ANESTHESIA

The introduction of rapid-onset, short-acting volatile anesthetics (e.g., desflurane and sevoflurane), opioids (e.g., remifentanyl), and muscle relaxants has enabled earlier recovery from anesthesia and thereby facilitated ambulatory and fast track surgery.⁴ Although use of these newer general anesthetic agents has resulted in quicker recovery of vital organ function after minor surgical procedures, it has not been shown to decrease stress responses or mitigate organ dysfunction after major procedures.

Regional anesthetic techniques (e.g., peripheral nerve blocks and spinal or epidural analgesia), on the other hand, have several advantages in addition to providing anesthesia. Such advantages include improved pulmonary function, decreased cardiovascular demands, reduced ileus, and more effective pain relief. Neural blockade is the most effective technique for providing postoperative pain relief, and it has been shown to reduce endocrine and metabolic responses to surgery [see 1:6 *Postoperative Pain*]. For a pronounced reduction in perioperative stress after a major operation, continuous epidural analgesia for 24 to 72 hours is necessary.^{5,6} A meta-analysis of randomized trials evaluating regional anesthesia (primarily involving patients undergoing operations on the lower body) found that morbidity was 30% lower with regional anesthesia than with general anesthesia.⁷ However, the effect of continuous epidural analgesia on outcome after major abdominal or thoracic procedures has been questioned in the past several years. In three large randomized trials,⁸⁻¹⁰ no beneficial effect on overall morbidity could be demonstrated, except for a slight improvement in pulmonary outcome, and the duration of hospi-

talization was not reduced. It should be remembered, however, that in these studies, either an epidural opioid regimen or a predominantly epidural opioid regimen was employed and that the perioperative care regimens either were not described or were not revised according to current scientific data regarding the use of nasogastric tubes, early oral feeding, mobilization, and other care parameters.³ We believe, therefore, that for further assessment of the role of continuous epidural local analgesic regimens that include local anesthetics in improving outcome, an integrated approach within the context of fast track surgery is required.⁶

Perioperative measures should also be taken to preserve intraoperative normothermia. Hypothermia may lead to an augmented stress response during rewarming, impaired coagulation and leukocyte function, and increased cardiovascular demands. Preservation of intraoperative and early postoperative normothermia has been shown to decrease surgical site infection, intraoperative blood loss, postoperative cardiac morbidity, and overall catabolism.¹¹

REDUCTION OF SURGICAL STRESS

The neuroendocrine and inflammatory stress responses to surgery increase demands on various organs, and this increased demand is thought to contribute to the development of postoperative organ system complications. At present, the most important of the techniques used to reduce the surgical stress response are regional anesthesia, minimally invasive surgery, and pharmacologic intervention (e.g., with steroids, beta blockers, or anabolic agents).¹²

Neural blockade with local anesthetics reduces endocrine and metabolic (specifically, catabolic) activation and sympathetic stimulation, thereby decreasing the demands placed on organs and reducing loss of muscle tissue; however, regional anesthetic techniques have no relevant effect on inflammatory responses.^{5,6}

Minimally invasive surgical techniques clearly decrease pain and lessen inflammatory responses,¹³⁻¹⁵ but they appear to have relatively little, if any, effect on endocrine and metabolic responses.

Pharmacologic intervention with a single dose of a glucocorticoid (usually dexamethasone, 8 mg) given before a minor procedure has led to reduced nausea, vomiting, and pain, as well as to decreased inflammatory responses (interleukin-6), with no observed side effects.^{16,17} This intervention may facilitate recovery from minor (i.e., ambulatory) procedures¹⁸; however, the data from major procedures are inconclusive. The use of perioperative beta blockade to reduce sympathetic stimulation and thereby attenuate cardiovascular demands has been shown to reduce cardiac morbidity,¹⁹ as well as to reduce catabolism in burn patients [see *Elements of Contemporary Practice:6 Risk Stratification, Preoperative Testing, and Operative Planning*].^{20,21} Perioperative beta blockade may therefore become an important component of efforts to facilitate recovery in fast track surgical programs.

For patients whose nutritional status is normal, oral feeding ad libitum is appropriate in the postoperative period. For patients who are elderly or nutritionally depleted, nutritional supplementation, administration of an anabolic agent (e.g., oxandrolone or another anabolic steroid,²²⁻²⁴ insulin,²⁵ or growth hormone [GH]^{26,27}) to enhance deposition of lean tissue, or both may be beneficial. Most of the studies addressing the use of anabolic agents have focused on critically ill catabolic patients, in whom both indirect effects (e.g., improved nitrogen balance²⁶) and direct effects (e.g., improved wound healing and decreased length of stay with GH in burned children²⁷ and decreased mortality with insulin in critically ill patients²⁵) on outcome have been demonstrated. In a study published in 2000, a group of elderly patients undergoing opera-

tions for hip fracture received either low-dose GH (20 mg/kg/day) or placebo.²⁸ Overall, those in the GH group were able to return to their prefracture living situation earlier than those in the placebo group. A 1999 study reported increased mortality when GH was administered to ICU patients,²⁹ but a 2001 meta-analysis failed to confirm this observation.³⁰ More work is necessary before definitive conclusions can be formed in this regard.

Postoperative insulin resistance is an important metabolic factor for catabolism. There is evidence to suggest that preoperative oral or intravenous carbohydrate feeding may reduce postoperative insulin resistance.³¹ Whether this approach yields clinical benefits in terms of improved recovery remains to be determined,^{31,32} but its simplicity, its clear pathophysiologic rationale, and its low cost make it a potentially attractive option.

CONTROL OF NAUSEA, VOMITING, AND ILEUS

The ability to resume a normal diet after a surgical procedure (whether minor or major) is essential to the success of fast track surgery. To this end, postoperative nausea, vomiting, and ileus must be controlled. Principles for rational prophylaxis of nausea and vomiting have been developed on the basis of systematic reviews³³: for example, 5-HT₃ receptor antagonists, droperidol, and dexamethasone have been shown to be effective in this regard, whereas metoclopramide is ineffective. There is some reason to think that multimodal antiemetic combinations may be superior to single antiemetic agents; unfortunately, the data currently available on combination regimens are relatively sparse. In addition, analgesic regimens in which opioids are cut back or eliminated have been shown to decrease postoperative nausea and vomiting.

Paralytic ileus remains a significant cause of delayed recovery from surgery and contributes substantially to postoperative discomfort and pain. Of the various techniques available for managing ileus,^{34,35} continuous epidural analgesia with local anesthetics is the most effective, besides providing excellent pain relief. Now that cisapride has been taken off the market, no effective anti-ileus drugs are available. In a 2001 study, however, a peripherally acting mu opioid receptor antagonist significantly reduced nausea, vomiting, and ileus after abdominal procedures, without reducing analgesia.³⁶ If further studies confirm these findings, use of peripherally acting opioid antagonists may become a popular and effective way of improving postoperative recovery; this treatment is simple and apparently has no major side effects.

ADEQUATE TREATMENT OF POSTOPERATIVE PAIN

Despite ongoing development and documentation of effective postoperative analgesic regimens—such as continuous epidural analgesia in major operations, patient-controlled analgesia (PCA), and multimodal (balanced) analgesia that includes nonsteroidal anti-inflammatory drugs as well as stronger agents³⁷⁻³⁹ [see *1:6 Postoperative Pain*]⁴⁰—postoperative pain still is too often inadequately treated. Improved pain relief, facilitated by an acute pain service,⁴⁰ is a central component of any fast track surgery program and is a prerequisite for optimal mobilization and oral nutrition, as well as a valuable aid in reducing surgical stress responses.³⁷

APPROPRIATE USE OF TUBES, DRAINS, AND CATHETERS

There is substantial support in the literature for the idea that nasogastric tubes should not be used routinely in patients undergoing elective abdominal surgery.^{1,2} Randomized trials indicated that drains offered little benefit after cholecystectomy, joint replacements, colon resection, thyroidectomy, radical hysterectomy, or

pancreatic resection^{1,3,41} but that they might limit seroma formation after mastectomy.^{1,3} Such postmastectomy drainage does not necessarily impede hospital discharge, and the patient generally may be treated on an outpatient basis. Urinary catheterization has been routinely performed after many operations, but scientific documentation of the requirement for this measure is often lacking. In general, catheterization beyond 24 hours is not recommended with colorectal procedures, except with the lowest rectal procedures, for which 3 to 4 days of catheterization may be indicated.³

Although tubes, drains, and catheters may lead to morbidity only when used for extended periods, they do tend to hinder mobilization, and they can raise a psychological barrier to the patient's active participation in postoperative rehabilitation. Therefore, such devices should be used not routinely but selectively, in accordance with the available scientific documentation.

NURSING CARE, NUTRITION, AND MOBILIZATION

Postoperative nursing care should include psychological support for early rehabilitation, with a particular focus on encouraging the patient to resume a normal diet and become ambulatory as soon as possible. Early resumption of an oral diet is essential for self-care; furthermore, according to a 2001 meta-analysis of controlled trials, it may reduce infectious complications and shorten hospital stay after abdominal procedures, without increasing the risk of anastomotic dehiscence.⁴² In addition, early resumption of enteral feeding may reduce catabolism and may be facilitated by the methods used to reduce postoperative nausea, vomiting, and ileus (see above).

Postoperative bed rest is undesirable because it increases muscle loss, decreases strength, impairs pulmonary function and tissue oxygenation, and predisposes to venous stasis and thromboembolism.³ Accordingly, every effort should be made to enforce postoperative mobilization; adequate pain relief is a key adjuvant measure in this regard.

Organization is essential for good postoperative nursing care: a prescheduled care map should be drawn up, with goals for rehabilitation listed for each day.

DISCHARGE PLANNING

Given that a primary result of fast track surgery is reduced length of hospitalization, discharge planning must be a major consideration in the preoperative patient information program, as well as during hospitalization. Careful, detailed discharge planning is essential for reducing readmissions and increasing patient safety and satisfaction. The discharge plan should include (1) detailed information on the expected time course of recovery, (2) recommendations for convalescence, and (3) encouragement of enteral intake and mobilization. For patients with a significant degree of postoperative disability, various acute care facilities are available after hospital discharge. It should be kept in mind, however, that the integrated care approach fundamental to fast track surgery is specifically intended as a way of limiting or preventing such disability, thereby reducing patients' need for and dependence on postdischarge care facilities.

Reported Results

Ongoing efforts to formulate multimodal strategies aimed at improving postoperative outcome have led to the development of a variety of fast track surgical programs [see Table 1]. Most of the studies published to date have been descriptive ones reporting consecutive patient series from single centers, the findings from which have often been confirmed by other groups using the same

or a slightly modified fast track care program. On the whole, the preliminary results from these studies are very positive: fast track surgery is associated with shorter hospital stays, reduced or at least comparable morbidities, and low readmission rates, with no apparent decrease in safety.

Studies of fast track surgery in which organ function was assessed postoperatively and compared with organ function after traditional care found fast track surgery to be associated with earlier ambulation,^{43,44} superior postoperative muscle function,⁴⁴ improved oral nutritional intake,⁴⁵ better preservation of lean body mass,^{43,45} reduced postoperative impairment of pulmonary function,⁴³ earlier recovery of GI motility,⁴⁶ and mitigation of the decrease in exercise capacity and impairment of cardiovascular response to exercise that are usually expected after an operation.⁴³ The few randomized trials performed to date (mostly involving patients undergoing cholecystectomy, colonic resection, or mastectomy) reported that fast track programs increased or at least maintained patient satisfaction while achieving major cost reductions.

Future Developments

The initial promising results from the fast track surgical programs studied suggest that such programs can achieve major care improvements in terms of reducing postoperative stay. At present, however, sufficient scientific documentation is lacking for many commonly performed major operations. Thus, there is a need for additional data—in particular, data on the potential positive effects of fast track surgery on postoperative morbidity. The necessary data would probably be best obtained through multicenter trials using identical protocols. Randomized trials within the same unit that allocate some patients to suboptimal care recommendations for pain relief, mobilization, and nutrition would be difficult to perform, if not unethical, though a few such reports have been published on colon surgery patients.^{44,47}

As yet, it has not been conclusively demonstrated that reducing the duration of hospitalization necessarily reduces morbidity,⁴⁸ though data from studies addressing colonic and vascular procedures suggest that nonsurgical (i.e., cardiopulmonary and thromboembolic) morbidity may be reduced and overall postoperative recovery (assessed in terms of exercise performance and muscle power) enhanced. More study is required in this area. Future trials should also focus on identifying any factors that might be limiting even more aggressive early recovery efforts, so that more effective fast track programs can be designed. Finally, studies are needed to identify potential high-risk patient groups for whom fast track surgery may not be appropriate or who may need to be hospitalized for slightly longer periods to optimize organ function.⁴⁷

There has been considerable interest in whether the use of critical pathways improves postoperative care. Preliminary studies involving coronary artery bypass grafting, total knee replacement, colectomy, thoracic procedures, and hysterectomy suggested that critical pathways may reduce length of hospital stay, but the reduction is no greater than can be observed in neighboring hospitals that do not use critical pathways.⁴⁹ Thus, the initial enthusiasm for critical pathways notwithstanding, conclusive evidence that they have a beneficial effect on postoperative care is still lacking. The continuously decreasing length of stay noted in hospitals without fast track programs may be partly attributable to the intense competition within the health care system, which can lead to changes in care principles even without the formal adoption of critical pathways or similar systems.⁴⁹

All of the studies on the economic implications of fast track surgical programs and critical pathways have documented substantial

Table 1 Results from Selected Fast Track Surgical Programs

Type of Operation	Postoperative Hospital Stay	Comments and Other Findings
Abdominal procedures		
Inguinal hernia repair ⁵⁹⁻⁶¹	1.5–6 hr	Large consecutive series using local infiltration anesthesia in > 95%, with one series ⁵⁹ using unmonitored anesthesia; documented low morbidity, with no urinary retention; patient satisfaction ~90%, cost reduction > \$250 with local anesthesia
Cholecystectomy (laparoscopic, ⁶²⁻⁶⁷ mini-incision ⁶⁸)	> 80% discharge on same day	Large consecutive series, with documented safety and patient satisfaction > 80%; cost reduction of \$750/patient in randomized study ⁶⁴ ; recovery of organ functions within 2–3 days, with <1 wk convalescence ⁶⁷ ; similar results with mini-incision in consecutive series ⁶⁸
Fundoplication ^{69,70}	> 90% < 23 hr	Large consecutive series with documented safety ⁷⁰
Open ^{43,44,46,47,56,71-76} and laparoscopic ^{72,77-79} colorectal procedures	2–4 days	Consecutive series including high-risk patients; reduced cardiopulmonary morbidity, readmission rates 0%–15%; no documented advantages of laparoscopy-assisted colonic resection, though costs may be reduced ⁷² ; ileus reduced to < 48 hr in > 90% of patients, ^{46,56} with improved muscle and pulmonary function in fast track patients and better preservation of postoperative body composition ⁴³ ; one randomized study showed similar morbidity, readmissions, and satisfaction with fast track versus traditional care ⁴⁷
Complex pelvic-colorectal procedures ^{80,81}	3–6 days	Short stay ⁸⁰ (~4–6 days) even with additional stoma; low readmission rate (7%)
Rectal prolapse ⁸²	80% < 24 hr	Consecutive series (N = 63) with Altemeier repair; 5% readmission rate (nonserious indications)
Pancreaticoduodenectomy, ^{83,84} complex biliary tract procedures ⁸⁵	—	Hospital stay decreased by implementation of clinical pathway
Mastectomy ⁸⁶⁻⁹⁰	90% < 1 day	Large cumulative series; documented safety and major cost reduction with high patient satisfaction; no increased morbidity with fast track, but less wound pain and improved arm movement and no increase in risk of psychosocial complications
Vascular procedures		
Carotid endarterectomy ⁹¹⁻⁹⁴	90% < 1 day	Surgery done with local anesthesia; specialized nurses and wards
Lower-extremity arterial bypass ⁹⁵	2–3 days	Large series (N = 130); documented safety
Abdominal aortic aneurysmectomy ^{96,97}	~3 days	Preliminary studies (N = 50 ⁹⁶ and N = 77 ⁹⁷); documented early recovery and safety; one study with epidural analgesia, ⁹⁷ one without ⁹⁶
Urologic procedures		
Radical prostatectomy ⁹⁸	~75% 1 day	Large consecutive series (N = 252); documented safety and patient satisfaction
Laparoscopic adrenalectomy ⁹⁹⁻¹⁰¹	< 1 day	Small series; safety and low morbidity suggested
Cystectomy ^{102,103}	7 days	Improved mobilization, bowel function, and sleep recovery with fast track surgery ¹⁰² ; low mortality; ileus a problem ^{102,103}
Laparoscopic donor nephrectomy ¹⁰⁴	< 1 day	Preliminary study (N = 41); low readmission rate (2%)
Open donor nephrectomy ¹⁰⁵	2 days	—
Pulmonary procedures ¹⁰⁶⁻¹¹⁰	~1 day in some series, ^{106,107} ~4–5 days in others	Shortest stay with fast track protocol including revision of drainage principles ^{106,107} ; safety with very early discharge suggested
Other procedures		
Craniotomy ¹¹¹	~40% < 24 hr	Large consecutive series (N = 241) including tumor surgery; local anesthesia used; low readmission rate; safety suggested
Parathyroid procedures ¹¹²	~90% ambulatory	Selected consecutive series (N = 100); regional anesthesia and intraoperative adenoma localization employed; documented safety
Vaginal procedures ¹¹³	~1 day	Consecutive series (N = 108); surgery done with local anesthesia

cost savings. It should, however, be borne in mind that the last portion of a hospital stay is much less expensive than the initial portion; thus, the cost savings in this area may turn out to be smaller than they would at first appear.⁵⁰⁻⁵² This caveat should not hinder further development and documentation of fast track surgery, because inherent in the concept is the idea that revision and optimization of perioperative care may also reduce morbidity,

thereby achieving additional cost savings. As noted, the large-scale data with detailed patient description and stratification that are needed to clarify the improvements achieved by fast track surgery are, unfortunately, lacking at present, but so far, all indications are that postoperative morbidity is comparable or reduced.

A commonly expressed concern is that fast track surgery might increase the burden on general practitioners and other parts of the

nonhospital care system. The evidence currently available clearly indicates that increased use of ambulatory surgery is safe and is associated with a very low readmission rate.^{53,54} After major procedures such as colorectal surgery, however, readmissions are often unpredictable, and the readmission rate is not significantly reduced by keeping patients in the hospital for an additional 2 to 3 days.^{55,56} Moreover, in some studies of patients who have undergone coronary bypass⁵⁷ and hip replacement,⁵⁸ earlier discharge and hospital cost savings have been offset by increased use of postacute rehabilitation services. Thus, any assessment of the costs associated with fast track surgery should include the total period during which care (including both hospital care and rehabilitation care) is delivered.

Again, however, it should be emphasized that the basic concept of fast track surgery implies control of perioperative pathophysiology with the aim of enhancing recovery and thereby reducing the need for postdischarge care. The relatively few published studies that

addressed patient functional status after fast track colonic surgery suggested that muscle function, exercise capacity, and body composition are better preserved with this approach than with traditional care, in which surgical stress, insufficient nutrition, and prolonged immobilization typically lead to significant deterioration of organ function. Accordingly, an optimal fast track surgery regimen should aim at early recovery of organ function, not just early discharge.

In summary, the basic concept of fast track surgery, which could be expressed as multimodal control of perioperative pathophysiology, seems to be a highly promising approach to improving surgical outcome. We believe that the principles and techniques embodied in this approach will eventually be integrated into the care of all surgical patients. To this end, resources should be allocated for evaluation and documentation of the effects of fast track surgery and related systems on cost, postoperative morbidity, safety, and overall patient well-being.

1 ORAL CAVITY LESIONS

Kiran Kakarala, MD, Sook-Bin Woo, DMD, MMSc, and Keith G. Saxon, MD, FACS

Approach to Oral Cavity Lesions

The oral cavity is a complex structure that plays a role in many important functions, including mastication, swallowing, speech, and respiration. It extends from the vermilion border of the lips to the oropharynx and is separated from the oropharynx by the anterior tonsillar pillars, the junction of the hard and soft palates, and the junction between the base of the tongue and the oral tongue at the circumvallate papillae. Subsites of the oral cavity include the lips, buccal mucosa, alveolus, retromolar trigone, tongue, floor of the mouth, and hard palate [see Figure 1].

In most cases, lesions of the oral cavity reflect locally confined processes, but, on occasion, they are manifestations of systemic disease. The cause of an oral cavity lesion can usually be identified by the history and the physical examination; however, it is most often determined definitively by either a response to a therapeutic trial or a biopsy. A systematic classification of oral cavity lesions facilitates the development of a differential diagnosis. One approach to classification is based on the appearance of the lesion (e.g., white, red, pigmented, ulcerative, vesiculobullous, raised, or cystic). Another approach is first to categorize the lesion as either neoplastic or nonneoplastic and then to further divide the nonneoplastic lesions into various subcategories (e.g., infectious, inflammatory, vascular, traumatic, and tumorlike) [see Table 1]. In the following discussion, we adopt the second approach.

Clinical Evaluation

HISTORY

The onset, duration, and growth rate of the oral lesion should be determined. Inflammatory lesions usually have an acute onset and are self-limited, and they may be recurrent. Neoplasms tend to exhibit progressive enlargement; a rapid growth rate is suggestive of malignancy. It is often possible to identify specific events (e.g., upper respiratory tract infection, oral trauma, or medications) that precipitated the lesions. Both malignancies and inflammatory conditions may be associated with various non-specific symptoms, including pain and dysphagia. Symptoms suggestive of malignancy include trismus, bleeding, a change in denture fit or occlusion, facial sensory changes, and referred otalgia. Fever, night sweats, and weight loss may occur in various settings but are particularly associated with lymphomas and systemic inflammatory conditions. Some oral lesions are identified without presenting signs or symptoms as incidental findings noted during a general dental or medical examination.

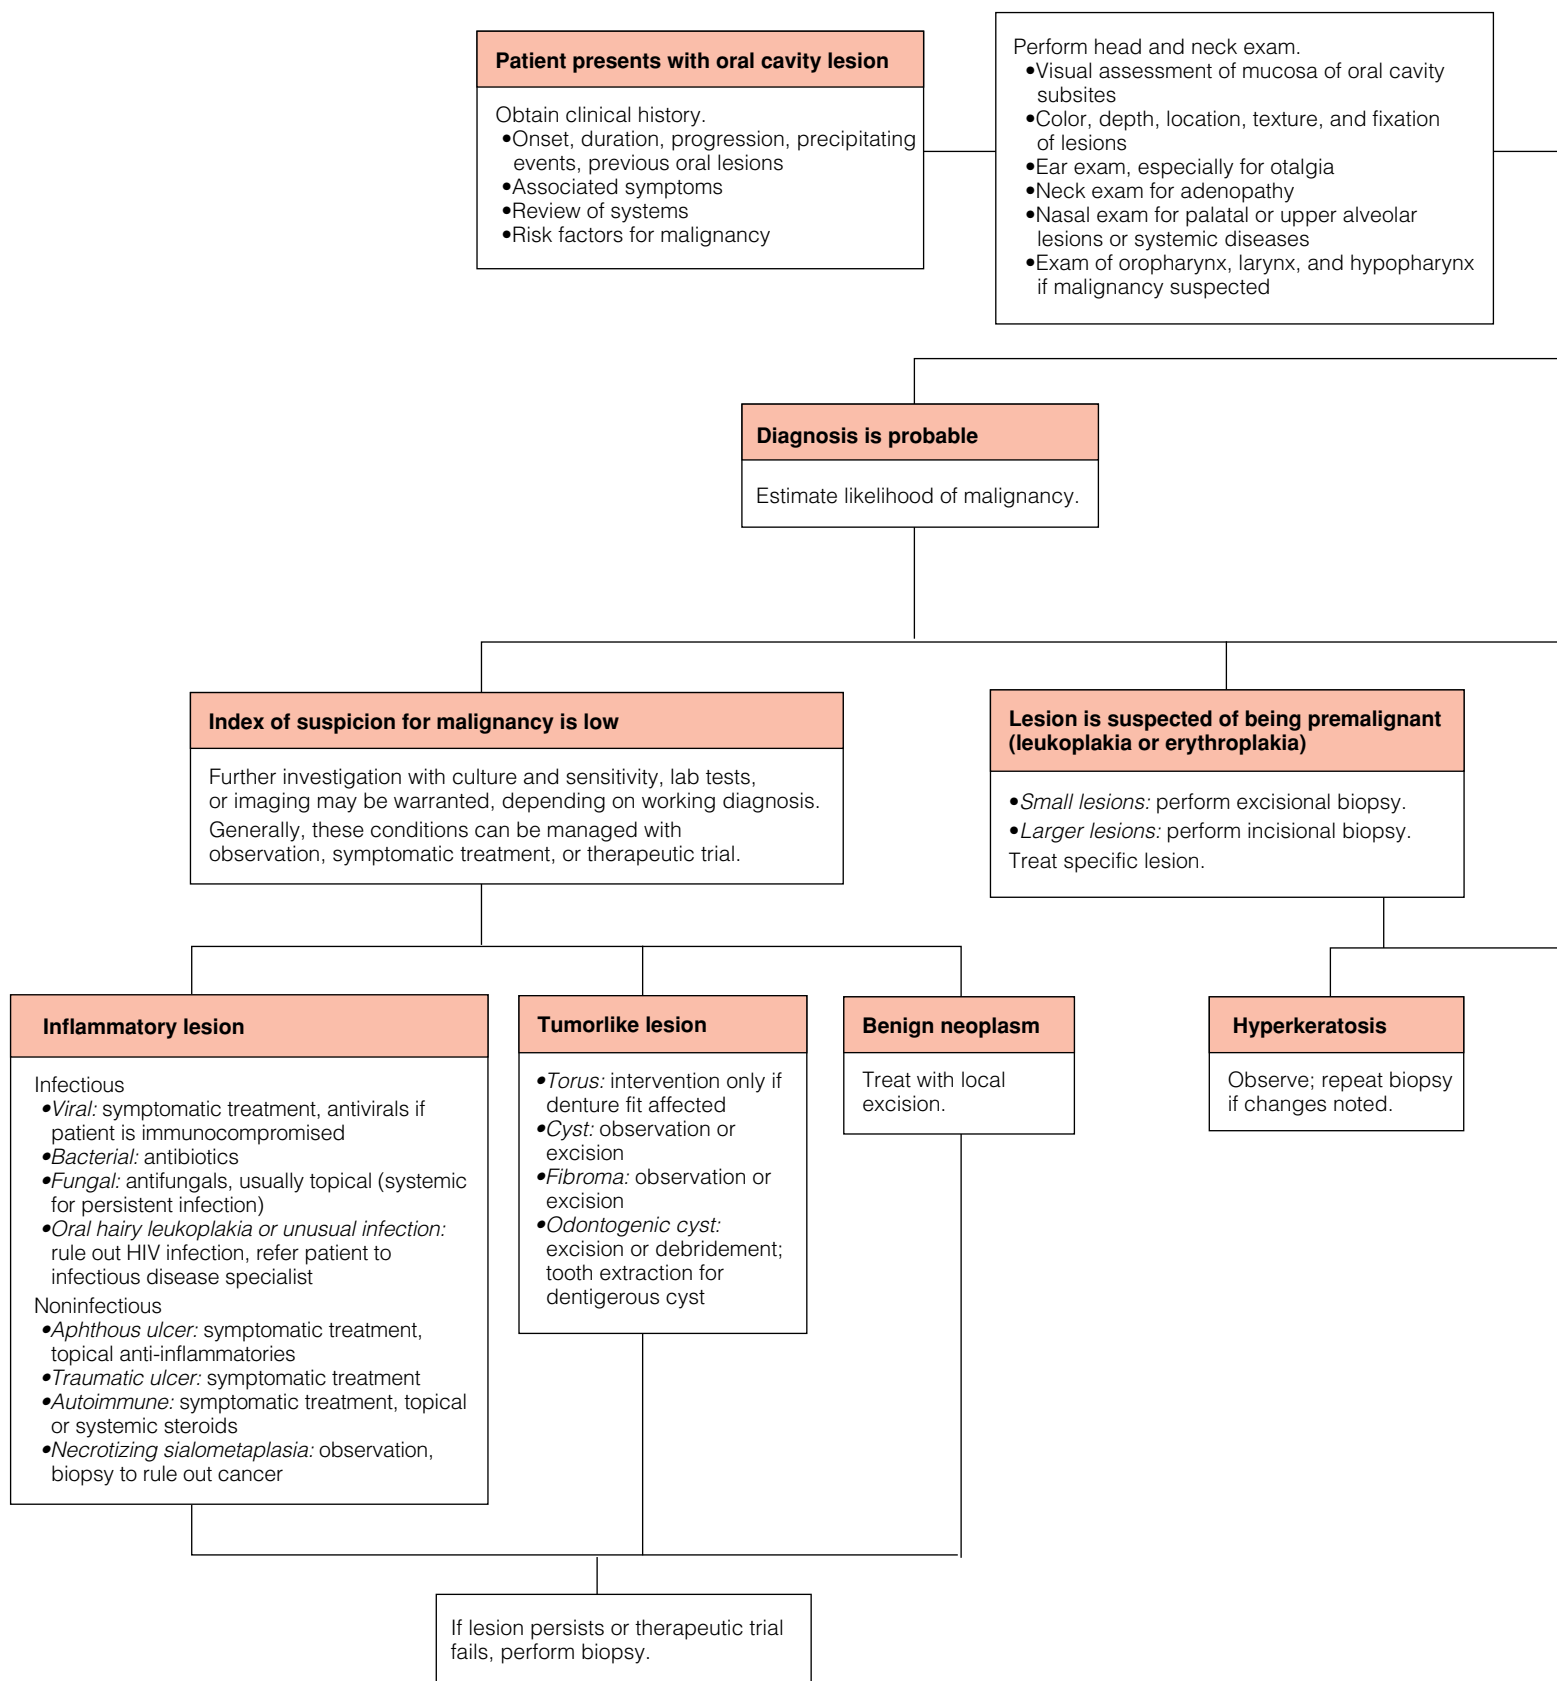

Figure 1 Depicted are the major anatomic subsites of the oral cavity.

A review of systems may uncover signs (e.g., rashes or arthritis) that suggest a possible autoimmune disorder. The medical history should always address previous or current connective tissue diseases, malignancies, radiation therapy, chemotherapy, and HIV infection. It is especially important to elicit a medication history because many classes of medications cause drug eruptions that involve the oral mucosa: for instance, well over 100 medications are associated with lichenoid drug reaction, and even more are associated with xerostomia. Use of alcohol or tobacco is a notable risk factor for the development of oral cavity carcinoma, as is a previous head and neck carcinoma. The quantity of alcohol or tobacco consumed should be determined because a dose-response relationship exists between the level of use and the risk of cancer. Other risk factors for oral cavity carcinoma include sun exposure (lip cancer), human papillomavirus infection, and nutritional deficiencies. Radiation exposure is a risk

Approach to Oral Cavity Lesions

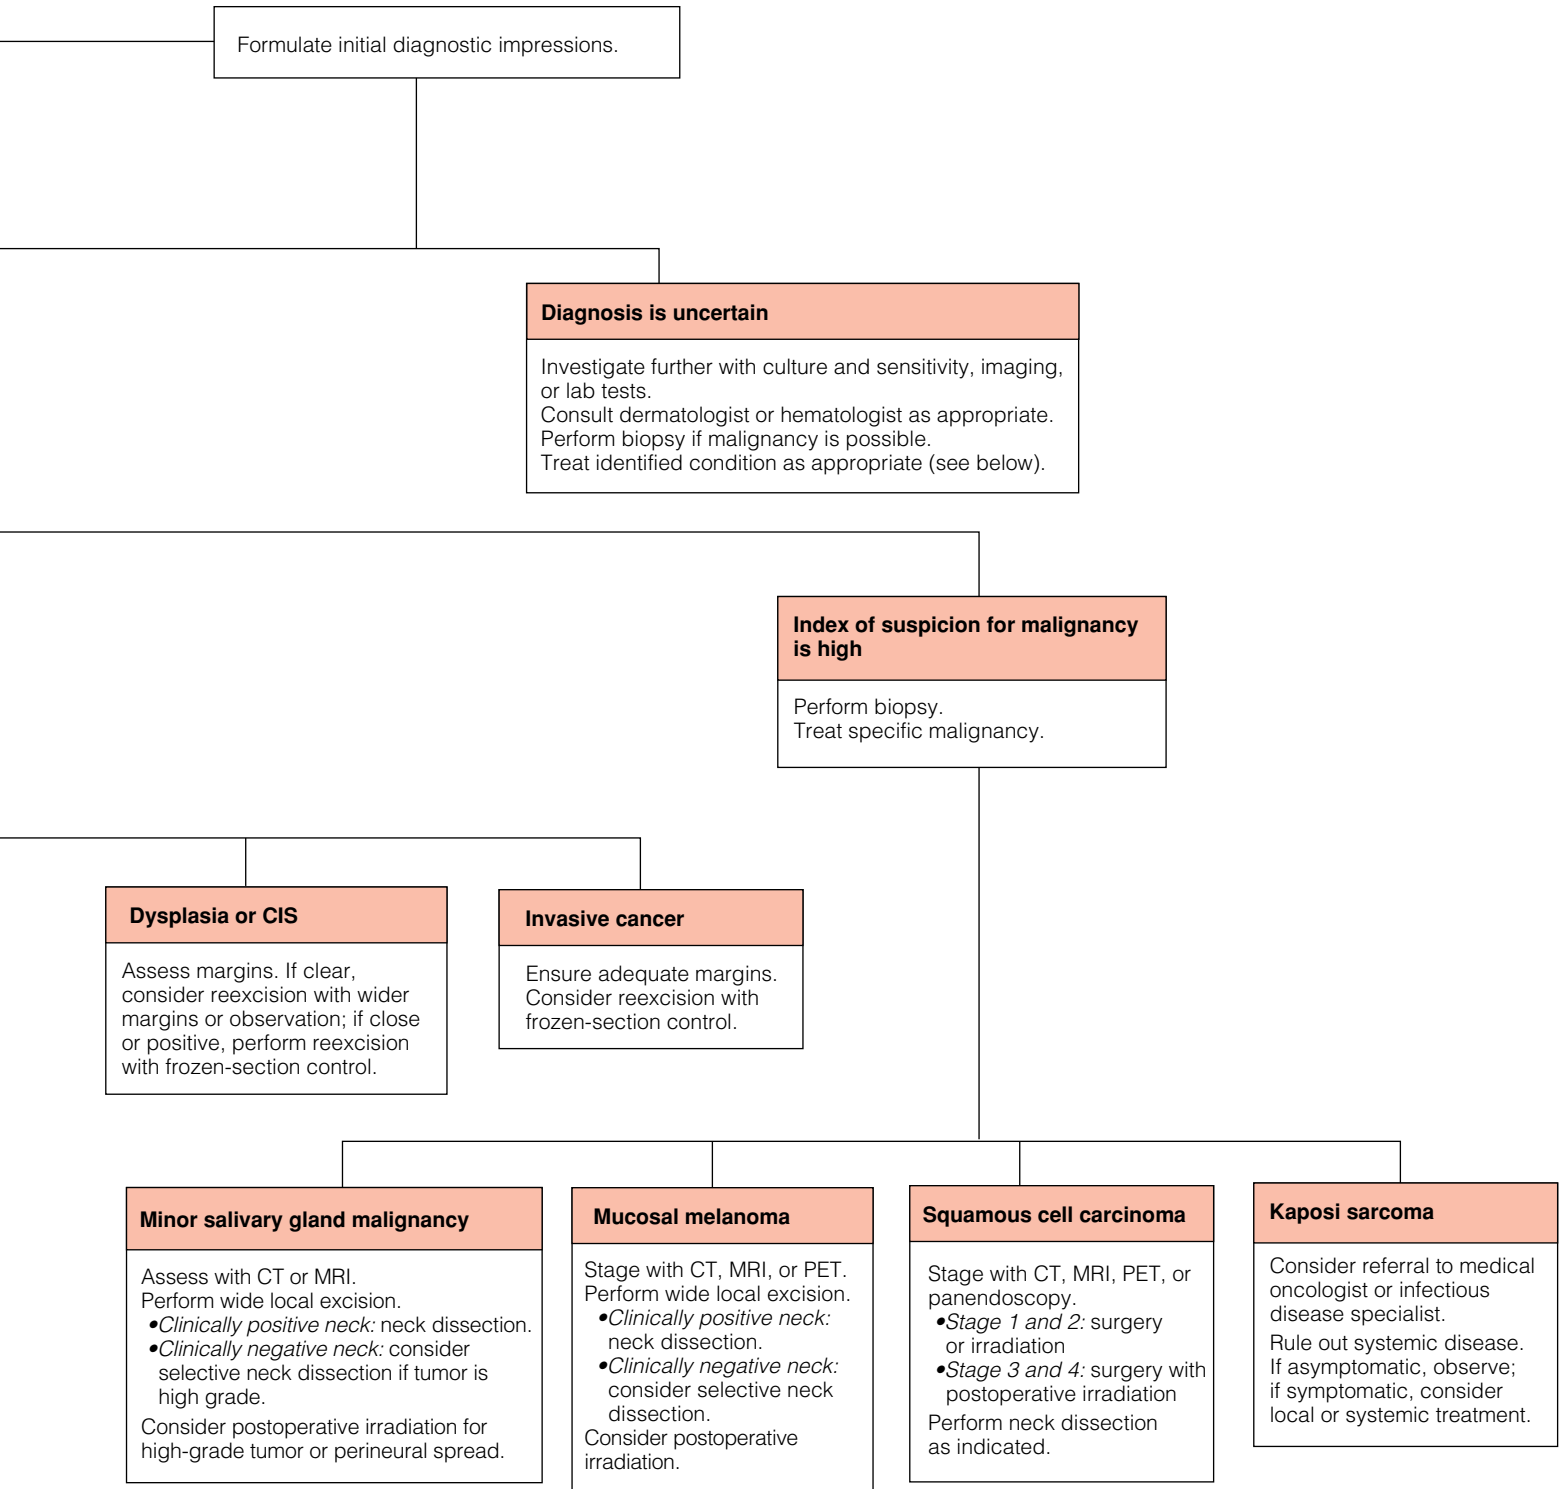

Table 1 Differential Diagnosis of Oral Cavity Lesions Based on Etiology

Inflammatory lesions
Infectious
Viral
Herpes simplex
Herpes zoster
Cytomegalovirus
Herpangina
Hand, foot, and mouth disease
Oral hairy leukoplakia (Epstein-Barr virus)
Bacterial
Mycobacterial infection
Syphilis
Gingivostomatitis
Fungal
Candidiasis
Coccidioidomycosis
Noninfectious
Recurrent aphthous stomatitis
Traumatic ulcer
Autoimmune disorders
Behçet syndrome
Systemic lupus erythematosus
Wegener granulomatosis
Sarcoidosis
Amyloidosis
Pemphigus and pemphigoid
Pyogenic granuloma
Necrotizing sialometaplasia
Lichen planus
Tumorlike lesions
Mucocoele
Ranula
Tori
Fibroma
Odontogenic cysts
Neoplasms
Benign
Squamous papilloma
Minor salivary gland neoplasms
Ameloblastoma
Hemangioma
Granular cell tumor
Brown tumor
Neuroma, schwannoma, neurofibroma
Osteoma, chondroma
Malignant
Squamous cell carcinoma
Verrucous carcinoma
Minor salivary gland malignancies
Mucoepidermoid carcinoma
Adenoid cystic carcinoma
Polymorphous low-grade adenocarcinoma
Mucosal melanoma
Kaposi sarcoma
Lymphoma
Osteosarcoma

factor for soft tissue sarcoma, lymphoma, and minor salivary gland tumors, and HIV infection is a risk factor for Kaposi sarcoma.

PHYSICAL EXAMINATION

The head and neck should be examined in an organized and systematic manner. Illumination with a headlight or a reflecting mirror facilitates oral examination by freeing the examiner's hands for use in retracting the cheeks and the tongue.

The mucosa of the oral cavity is evaluated at each of the oral subsites. Any trismus should be noted, as should the general health of the teeth and the gingiva. Percussion of carious teeth with pulpitis often elicits pain, although this is not always the case if caries is shallow or pulpal necrosis is present. Palpation of the tongue, the floor of the mouth, and the oral vestibule is an essential component of oral examination. Palpation of the submandibular and submental regions is best performed bimanually.

Oral lesions should be characterized in terms of color, depth, location, texture, fixation, and other applicable attributes. When cancer is present, tenderness, induration, and fixation are common. Invasion of surrounding structures (e.g., the mandible, the parotid duct, or the teeth) by a malignant lesion should be noted. Physical examination is not a definitive means of detecting mandibular invasion, because tumor fixation can be secondary to other factors and cortical invasion can occur with minimal fixation.^{1,2} In addition, lesions in some areas of the oral cavity (e.g., the hard palate and the attached gingiva) almost always appear to be fixed.

A history of otalgia warrants otoscopic examination. Otalgia in the absence of any identifiable pathologic condition of the ear often represents referred pain from a malignancy of the upper aerodigestive tract. The presence of otalgia in a middle-aged person should always trigger a search for an underlying cause. The nasal cavity should be examined with a speculum to rule out tumor extension in lesions of the hard palate, and transnasal fiberoptic pharyngoscopy and laryngoscopy should be done if a malignant neoplasm is a possibility or if a systemic condition is suspected that may also affect the nasal or pharyngeal mucosa.

Examination of the neck may reveal enlarged lymph nodes. Lymphadenopathy in an adult should be considered to represent metastatic cancer until proved otherwise. A benign ulcer in the oral cavity may cause a reactive adenopathy as a consequence of the associated inflammation, but in the setting of cervical lymphadenopathy, the initial diagnostic assumptions should emphasize the strong possibility of a primary oral cancer with metastases to the neck. Asymmetrical enlargement of the parotid or submandibular glands may result either from obstruction of the ducts by an oral cavity mass or from enlargement of nodes intimately associated with the glands. Symmetrical enlargement suggests a systemic process (e.g., Sjögren syndrome or HIV infection). The cranial nerves should be examined, with particular attention focused on the trigeminal, facial, and hypoglossal nerves.

Investigative Studies

The history and physical examination should narrow down the differential diagnosis and lead to a working diagnosis. If

a benign local process (e.g., aphthous stomatitis, traumatic ulcer, or viral infection) is suspected, no further investigation, other than reevaluation, may be needed. If the lesion persists or progresses, further investigation is warranted.

LABORATORY TESTS

Laboratory studies are usually not beneficial in the initial workup of oral cavity lesions. If a connective tissue disease

is suspected, serologic tests [see Table 2] and referral to a rheumatologist or another appropriate specialist may be considered.

IMAGING

The value of advanced imaging with computed tomography (CT), magnetic resonance imaging (MRI), or both in the management of oral cavity lesions has not been firmly established. Accordingly, judgment must be exercised. There is evidence to suggest that early oral cavity malignancies can be managed without either CT or MRI. Nevertheless, many clinicians obtain these studies in all cases of malignancy and in most cases of suspected malignancy. CT and MRI can help assess the size and location of the lesion and determine the degree to which surrounding structures are involved. In patients with oral cavity carcinoma, imaging facilitates the staging of tumors and the planning of treatment. In patients with cervical metastases, physical examination augmented by MRI and CT has a better diagnostic yield than physical examination alone. Bone-window CT scans are particularly helpful for assessing invasion of the mandible, the maxilla, the cervical spine, and the base of the skull. CT scans are highly sensitive and specific for detecting mandibular invasion.¹⁻³ MRI provides better soft tissue delineation than CT, with fewer dental artifacts, and therefore is particularly valuable for assessing malignancies of the tongue, the floor of the mouth, and the salivary glands. Loss of the usual marrow enhancement on T₁-weighted MRI images suggests bone invasion, although this is not a specific finding. Chest radiography, CT, or both may be employed to search for lung metastases or a second primary tumor.

Positron emission tomography (PET) is playing an increasingly important role in the workup of patients with head and neck carcinoma or mucosal melanoma. PET is useful for confirming the presence of a malignancy, as well as for assessing cervical and distant metastases; it is particularly valuable for detecting recurrent or persistent disease.⁴⁻⁶ The development of fused PET-CT images has allowed for greater accuracy in anatomically delineating tumors and planning treatment. Drawbacks of PET include frequent false positive results with active inflammation, high cost, and limited availability. In addition, the quality of the images obtained and the level

of technical experience available vary considerably among institutions. The role of PET imaging in the initial management and follow-up of head and neck cancer is still being defined.

BIOPSY

For oral cavity lesions that are suggestive of malignancy or are probably of neoplastic origin, biopsy is usually required. A brief observation period to allow reevaluation, with biopsy withheld, may be warranted if a response to therapy or spontaneous resolution is possible. The potential morbidity associated with a biopsy done in a previously irradiated region should be considered in deciding whether biopsy is advisable. Specimens are usually sent to the pathologist in 10% buffered formalin, but there are notable exceptions. If a lymphoma is suspected, specimens should be sent without formalin for genetic testing and flow cytometry. If an autoimmune disease is suspected, special tests requiring immunofluorescence are indicated, and specimens should be sent either fresh or in Michel solution. In addition, if fungal, mycobacterial, bacterial, or viral infection is suspected, a small portion of a specimen may be sent separately for culture. If there is an associated neck mass, fine-needle aspiration (FNA) may be performed to rule out metastatic disease.⁷ In general, FNA is not useful for biopsy of oral lesions: incisional biopsy is often technically easier and provides more tissue.

EXAMINATION UNDER ANESTHESIA AND PANENDOSCOPY

In patients with oral carcinoma, examination under anesthesia (EUA) and panendoscopy should be performed before definitive resection to assess the extent of the primary tumor and identify any synchronous tumors. Both EUA and panendoscopy are commonly performed in the operating room with the patient under general anesthesia. Panendoscopy involves endoscopic examination of the larynx, the oropharynx, the hypopharynx, the esophagus, and, occasionally, the nasopharynx. As a rule, assessment of the tumor and neck is more accurately performed when the patient is relaxed under a general anesthetic.

Diagnosis and Management of Specific Oral Cavity Lesions

INFLAMMATORY LESIONS

Infectious

Viral stomatitis may be caused by a number of different viruses, including herpes simplex virus (type 1 or type 2), varicella-zoster virus, and coxsackievirus [see Figure 2, a and b].⁸ It is most common in children and immunocompromised patients. The lesions of viral stomatitis are generally vesicular, occur in the oral cavity and the oropharynx, and erupt over the course of several days to form painful ulcers. Eruption may be preceded by local symptoms (e.g., burning, itching, or tingling) or systemic symptoms (e.g., fever, rash, malaise, or lymphadenopathy). The diagnosis is usually established by the history and the physical examination and may be confirmed by means of biopsy or viral culture.

Table 2 Serologic Tests for Diagnosing Connective Tissue Disease

Connective Tissue Disease	Serologic Tests
SLE	CBC, antinuclear antibody, anti-double-stranded DNA antibody, anti-Smith antibody
Sjögren syndrome	Antinuclear antibody, rheumatoid factor, anti-Ro (SS-A) and anti-La (SS-B) antibodies
Wegener granulomatosis	cANCA, serum creatinine level, urine microscopy
Sarcoidosis	Serum calcium and ACE levels

ACE = angiotensin-converting enzyme; cANCA = cytoplasmic antineutrophil cytoplasmic antibodies; CBC = complete blood count; SLE = systemic lupus erythematosus.

Figure 2 Shown are infectious lesions of the oral cavity: (a) primary herpes stomatitis of the buccal mucosa and soft palate; (b) primary herpes stomatitis of the tongue (in the same patient as in frame a); (c) oral candidiasis (pseudomembranous form); and (d) oral candidiasis (erythematous form).

Treatment of viral stomatitis primarily involves managing symptoms with oral rinses, topical anesthetics, hydration, and antipyretics. Systemic antiviral medications may shorten the course of herpetic stomatitis and are indicated in immunocompromised patients.⁹

Candidiasis is a common fungal infection of the oral cavity [see Figure 2, c and d]. *Candida albicans* is the species most commonly responsible; however, other *Candida* species can cause this condition as well, with *Candida glabrata* emerging as a growing problem in immunocompromised hosts. Factors predisposing to oral candidal infection include immunosuppression, use of broad-spectrum antibiotics, diabetes, prolonged use of local or systemic steroids, and xerostomia.¹⁰ Oral candidiasis presents in several different forms [see Table 3], of which pseudomembranous candidiasis (thrush) is the most common. This form is characterized by white, curdlike plaques on the oral mucosa that may be wiped off (with difficulty) to leave an erythematous, painful base (the Auspitz sign). Widespread oral and pharyngeal involvement is common. The diagnosis is based on the clinical appearance of the lesion and on evaluation of scrapings with the potassium hydroxide (KOH) test. Culture is generally not useful, because *Candida* is a common commensal oral organism.¹¹

Ideally, initial management of oral candidiasis is aimed at reversing the underlying condition, although this is not always

Table 3 Clinical Presentation of Oral Candidiasis	
Type of Oral Candidiasis	Presentation
Pseudomembranous	White, curdlike plaques on oral mucosa that when wiped off (with difficulty) leave erythematous, painful base
Hyperplastic	Thick white plaques on oral mucosa that cannot be rubbed off
Erythematous	Red, atrophic areas on palate or dorsum of tongue
Angular cheilitis	Cracking and fissuring at oral commissures

possible. Treatment typically involves either topically administered antifungal agents or, if infection is severe or topical therapy fails, systemically administered antifungals. Patients who are immunocompromised or have xerostomia may benefit from long-term prophylaxis.

Noninfectious

Recurrent aphthous stomatitis Aphthous stomatitis is a common idiopathic ulcerative condition of the oral cavity [see Figure 3, a and b]. The ulcers are typically painful and

Figure 3 Shown are noninfectious inflammatory lesions of the oral cavity: (a) minor aphthous ulcer of the lower lip; (b) minor aphthous ulcer of the upper lip; (c) necrotizing sialometaplasia of the hard palate; (d) resolution of necrotizing sialometaplasia without treatment (in the same patient as in frame c); (e) pyogenic granuloma of the upper alveolus; (f) reticular lichen planus involving the buccal mucosa; (g) lichen planus of the lateral tongue; (h) pemphigus vulgaris of the oral cavity, with an erythematous base after rupture of bullae (involving the left lateral tongue, the buccal mucosa, and the lip); and (i) traumatic ulcer of the tongue secondary to dental trauma.

may occur anywhere in the oral cavity and the oropharynx but are rarely found on the hard palate, the dorsal tongue, and the attached gingiva.^{9,12} Affected patients often have a history of lesions, beginning before adolescence. There are three different clinical presentations of recurrent aphthous stomatitis, of which minor aphthous ulcers are the most common [see Table 4].⁹ The diagnosis is made on the basis of the history and the physical examination; biopsy is reserved for lesions that do not heal or that grow in size.

Numerous therapies have been tried for recurrent aphthous stomatitis, most with only minimal success. The majority of aphthous ulcers heal within 10 to 14 days and require no treatment; however, patients with severe symptoms may require medical intervention. Temporary pain relief can be obtained with topical anesthetic agents (e.g., viscous lidocaine). Tetracycline oral suspension and antiseptic mouthwashes have also been used, with varying success.^{9,12} Topical steroids are the mainstay of therapy and may shorten the duration of the ulcers if applied during the early phase.^{11,12} These agents may be applied either in a solution (e.g., dexamethasone oral suspension, 0.5 mg/5 mL) or in an ointment (e.g., fluocinolone or clobetasol). Ointments work much better in the oral cavity than creams or gels do. Systemic steroids are indicated when the number of ulcers is large or when the outbreak has persisted for a long time.

Necrotizing sialometaplasia Necrotizing sialometaplasia is a rare benign inflammatory lesion of the minor salivary glands that resembles carcinoma clinically and histologically and is readily mistaken for it [see Figure 3c].⁸ This condition most commonly develops in white males in the form of a deep, sudden ulcer of the hard palate. The presumed cause is ischemia of the minor salivary glands resulting from infection, trauma, surgery, irradiation, or irritation caused

by ill-fitting dentures.⁹ Biopsy is usually necessary to rule out squamous cell carcinoma or a minor salivary gland malignancy. Review of the tissue by a pathologist well versed in head and neck pathology is essential. Characteristic histologic findings include coagulation necrosis of the salivary gland acini, ductal squamous metaplasia, preservation of the lobular architecture, and a nonmalignant appearance of squamous nests.¹³

Lesions resolve without treatment within 6 to 10 weeks [see Figure 3d].

Pyogenic granuloma A pyogenic granuloma is an aggregation of proliferating endothelial tissue [see Figure 3e] that occurs in response to chronic persistent irritation (e.g., from a calculus or a foreign body) or trauma.¹⁰ The lesion appears as a raised, soft, sessile or pedunculated mass with a smooth, red surface that bleeds easily and can grow rapidly.¹⁴ Surface ulceration may occur, but the ulcers are not invasive. The gingiva is the most common location, but any of the oral tissues may be involved.

Conservative excision with management of the underlying irritant is the recommended treatment. The classic presentation is in a pregnant woman, and hormonal influences may have an additional influence on recurrence.

Lichen planus Lichen planus is a common immune-mediated inflammatory mucocutaneous disease [see Figure 3, f and g].¹⁵ Clinically, idiopathic lichen planus is indistinguishable from lichenoid drug reaction. The reticular form of lichen planus is the most common one and presents as interlacing white keratotic striae on the buccal mucosa, the lateral tongue, and the palate.¹⁵ Lichen planus is usually bilateral, symmetrical, and asymptomatic.¹⁶ The symptomatic phases may wax and wane, with erythematous and ulcerative changes being the primary signs. Cutaneous lesions occur less frequently and appear as small, violaceous, pruritic papules. The diagnosis is generally made on the basis of the history and the physical examination; biopsy is not always necessary.

For asymptomatic lesions, no treatment is required other than observation. For painful lesions, which are more common with the erosive form of the disease, either topical or systemic steroids are appropriate.¹⁶ There is some controversy regarding the risk of malignant transformation; however, long-term follow-up is still recommended.¹⁶ The main risk posed by lichen planus may be the masking effect that the white striae cause, which can prevent the clinician from observing the early leukoplakic and erythroplakic changes associated with epithelial dysplasia.

Ulcer from autoimmune disease Oral ulcers may be the first manifestation of a systemic illness. The most common oral manifestation of systemic lupus erythematosus (SLE) is the appearance of painful oral ulcers in women of child-bearing age. Patients with Behçet disease present with the characteristic triad of painful oral ulcers, genital ulcers, and associated iritis or uveitis. Patients with Crohn disease or Wegener granulomatosis frequently manifest oral ulceration during the course of the illness. These disorders should be managed in conjunction with a rheumatologist.

Mucous membrane pemphigoid and pemphigus vulgaris are chronic vesiculobullous autoimmune diseases that frequently affect the oral mucosa [see Figure 3h]. In mucous

Table 4 Clinical Presentation of Aphthous Stomatitis

Type of Aphthous Ulcer	Presentation	Time to Resolution
Minor	Multiple painful, well-demarcated ulcers, < 1.0 cm in diameter, are noted, with yellow fibrinoid base and surrounding erythema; typically involve mobile mucosa, with tongue, palate, and anterior tonsillar pillar the most common sites	7–10 days, without scarring
Major (Sutton disease)	Ulcers, often multiple, may range in size from a few millimeters to 3 cm and may penetrate deeply with elevated margins; typically involve mobile mucosa, with tongue, palate, and anterior tonsillar pillar the most common sites	4–6 wk, with scarring
Herpetiform	Small (1–3 mm) ulcers occur in “crops” but are still limited to movable mucosal surfaces; gingival involvement, if present, is caused by extension from nonkeratinizing crevicular epithelium	1–2 wk

membrane pemphigoid, the antibodies are directed at the mucosal basement membrane, resulting in subepithelial bullae.¹⁶ These bullae rupture after 1 to 2 days to form painful ulcers, which may heal over a period of 1 to 2 weeks but often do not display a predictable periodicity. Oral pain is often the chief complaint, but there may be undetected ocular involvement that can lead to entropion and blindness.

Pemphigus vulgaris is a more severe disease than mucous membrane pemphigoid. In this condition, the antibodies are directed at intraepithelial adhesion molecules, leading to the formation of intraepithelial bullae.⁹ The blisters are painful and easily ruptured and tend to occur throughout the oral cavity and the pharynx.¹⁷ The Nikolsky sign (i.e., vesicle formation or sloughing when a lateral shearing force is applied to uninvolved oral mucosa or skin) is present in both pemphigus and pemphigoid. In most cases, biopsy with pathologic evaluation (including immunofluorescence studies) is helpful in establishing the diagnosis. Circulating antibodies may be present in either condition but are more common in pemphigus. Serologic tests may suffice to establish the diagnosis, without any need for biopsy. Management involves administration of immunosuppressive agents, often in conjunction with a dermatologist.

Traumatic ulcer Trauma (e.g., from tooth abrasion, tooth brushing, poor denture fit, or burns) is a common cause of oral mucosal ulceration [see Figure 3i]. The ulcers usually are painful but typically are self-limited and resolve without treatment. Topical anesthetic agents may be beneficial if pain is severe enough to limit oral intake.

Tumorlike Lesions

TORUS MANDIBULARIS AND TORUS PALATINUS

Palatal and mandibular tori are benign focal overgrowths of cortical bone [see Figure 4, a and b].¹⁰ They appear as slow-growing, asymptomatic, firm, submucosal bony masses developing on the lingual surface of the mandible or the midline of the hard palate.¹⁴ When these lesions occur on the labial or buccal aspect of the mandible and the maxilla, they are termed exostosis.¹⁸ Torus mandibularis tends to occur bilaterally, whereas torus palatinus arises as a singular, often lobulated mass in the midline of the hard palate. Surgical management is required only if the tori are interfering with denture fit.

MUCOCELE AND MUCOUS RETENTION CYST

A mucocele is a pseudocyst that develops when injury to a minor salivary gland duct causes extravasation of mucus, surrounding inflammation, and formation of a pseudocapsule [see Figure 4, c and d].¹⁴ Mucoceles are soft, compressible, bluish or translucent masses that may fluctuate in size. They are most commonly seen on the lower lip but also may develop on the buccal mucosa, anterior ventral tongue, and floor of the mouth. Only very rarely do they involve the upper lip; masses in the upper lip, even if they are fluctuant, should be assumed to be neoplastic, developmental, or infectious. Treatment involves excision of the mucocele and its associated minor salivary gland.

A ranula (from a diminutive form of the Latin word for frog) is a mucocele that develops in the floor of the mouth

as a consequence of obstruction of the sublingual duct,¹⁹ secondary either to trauma or to sublingual gland sialoliths. If the ranula extends through the mylohyoid muscle into the neck, it is referred to as a plunging ranula. A plunging ranula may present as a submental or submandibular neck mass. Imaging helps delineate the extent of the mass and may confirm the presence of a sialolith. The recommended treatment is excision of the ranula with removal of the sublingual gland and often the adjacent submandibular gland. Marsupialization is an option but is associated with a relatively high recurrence rate.^{19,20}

A mucous retention cyst (salivary duct cyst) is usually the result of partial obstruction of a salivary gland duct accompanied by mucous accumulation and ductal dilatation [see Figure 4e].¹⁹ It is a soft, compressible mass that may occur at any location in the oral cavity where minor salivary glands are present. Treatment involves surgical excision with removal of the associated minor salivary gland.

FIBROMA

A fibroma is a hyperplastic response to inflammation or trauma [see Figure 4, f and g].⁸ It is a pedunculated soft or firm mass with a smooth mucosal surface that may be located anywhere in the mouth. Such lesions are managed with either observation or local excision.

ODONTOGENIC CYST

A dentigerous cyst is an epithelium-lined cyst that, by definition, is associated with the crown of an unerupted tooth [see Figure 4h]. Such cysts cause painless expansion of the mandible or the maxilla. Treatment involves enucleation of the cyst and its lining and extraction of the associated tooth.²¹

An odontogenic keratocyst is a squamous epithelium-lined cyst that produces keratin. Bone resorption occurs secondary to pressure resorption and to inflammation caused by retained keratin. Management involves either excision or débridement and creation of a well-ventilated and easily maintained cavity.²²

Neoplastic Lesions

BENIGN

Squamous Papilloma

Squamous papilloma is one of the most common benign neoplasms of the oral cavity [see Figure 5, a and b].¹³ It usually presents as a solitary, slow-growing, asymptomatic lesion, typically less than 1 cm in diameter. It is well circumscribed and pedunculated and has a warty appearance.¹⁶ The palate and tongue are the sites most frequently affected¹³; occasionally, multiple sites are involved. The presumed cause is a viral infection, most likely human papillomavirus.²³

Papillomas are managed with complete excision, including the base of the stalk.

Giant Cell Lesions

Central giant cell granulomas, brown tumors of hyperparathyroidism, aneurysmal bone cysts, and lesions associated with genetic diseases (e.g., cherubism) may all be seen in the jaws. Of particular note is the aneurysmal bone cyst that may occur at sites of trauma, which, in theory, is the consequence

Figure 4 Shown are tumorlike lesions of the oral cavity: (a) torus mandibularis, with bilateral bony protuberances on the lingual surface of the mandible; (b) mandibular exostosis, with a unilateral bony protuberance on the labial-buccal surface of the mandible; (c) mucocele of the lip (note the bluish hue of the cystic lesion; cf. frame e); (d) mucocele of the floor of the mouth associated with the sublingual gland (ranula); (e) mucous retention cyst of the lower lip (presenting much like mucocele but appearing more transparent); (f) fibroma of the hard palate resulting from denture trauma; (g) fibroma of the lower lip; and (h) dentigerous cyst (a unilocular radiolucency surrounding the crown of an unerupted tooth, with no bone destruction).

of an organizing hematoma that leads to bony expansion and giant cell proliferation.²⁴ Eventually, erosion of the buccal cortex may occur with the development of facial swelling.

Management involves enucleation and curettage.^{24,25} The surgeon should be prepared for bleeding during treatment. The use of calcitonin or intralesional steroid injections is gaining popularity.²⁵

Minor Salivary Gland Neoplasms

The minor salivary glands are small, mucus-secreting glands that are distributed throughout the upper aerodigestive tract, with the largest proportion concentrated in the oral cavity. Minor salivary gland neoplasms are uncommon, but when they do occur, they are most likely to develop in the oral cavity. Within the oral cavity, the hard palate and the soft palate are the most common sites of minor salivary gland neoplasms; however, tumors involving the tongue, the lips, the buccal mucosa, and the gingivae have been described.

Approximately 30% of minor salivary gland neoplasms are benign. Of these benign lesions, the most common is pleomorphic adenoma, which presents as a painless, slow-growing submucosal mass [see Figure 5, c and d].^{13,26}

Pleomorphic adenoma is managed with complete surgical excision to clear margins. This tumor exhibits small, pseudopodlike extensions that may persist and cause recurrence if enucleation around an apparent capsule is attempted.

Granular Cell Tumor

A granular cell tumor is a benign neoplasm that is thought to arise from Schwann cells.¹³ It usually presents as a small, asymptomatic, solitary submucosal mass. The lateral border and the dorsal surface of the tongue are the sites where this tumor is most frequently found in the oral cavity.²⁷ Pathologic examination may reveal pseudoepitheliomatous hyperplasia, which is similar in appearance to well-differentiated squamous cell carcinoma.²⁸ This similarity has led to reports of

Figure 5 Shown are benign neoplasms of the oral cavity: (a) squamous papilloma of the frenulum; (b) squamous papilloma of the ventral tongue; (c) pleomorphic adenoma of the hard palate; (d) pleomorphic adenoma of the hard palate on coronal computed tomography (CT) (note the soft tissue thickening along the left hard palate, with no bone erosion or destruction); (e) ameloblastoma of the left angle and ramus of the mandible (a multilocular radiolucency); and (f) ameloblastoma on CT, with a soft tissue mass in the left mandible and erosion of the lingual plate of the mandible.

misdiagnosis on histopathologic evaluation. Accordingly, given the known rarity of squamous cell carcinoma of the dorsal surface of the anterior two thirds of the tongue, it may be prudent to obtain a second histopathologic opinion whenever a diagnosis of squamous cell carcinoma is rendered in this location. Treatment consists of conservative excision.²⁷

Ameloblastoma

Ameloblastoma is a neoplasm that arises from odontogenic (dental) epithelium, most frequently in the third and fourth decades of life [see Figure 5, e and f].^{8,26} It often presents as a painless swelling with bony enlargement. Approximately 80% of ameloblastomas involve the mandible and 20% the maxilla²⁹; the mandibular ramus is the most common site.²⁹ Ameloblastomas are usually benign but are often locally aggressive and infiltrative. Malignant ameloblastomas are rare but are notable for being associated with pain, rapid growth, and metastases.¹¹

On CT and panoramic jaw films, ameloblastomas typically appear as multilocular radiolucent lesions with a honeycomb appearance and scalloped borders.³⁰ These tumors are often

associated with an unerupted third molar tooth and, with the exception of the desmoplastic variant, rarely appear radiopaque. They may also appear unilocular on radiographic imaging.³¹ Histologic examination shows proliferating odontogenic epithelium with palisading peripheral cells that display reverse polarization of the nuclei.¹³

Appropriate management of ameloblastomas involves resection to clear margins. For mandibular ameloblastomas, either a marginal or a segmental mandibulectomy is done, depending on the relation of the lesion to the inferior cortical border. Curettage is associated with a high recurrence rate.²⁹ The prognosis for maxillary multicystic ameloblastoma is relatively poor because of the higher recurrence rate and the greater frequency of invasion of local adjacent structures (e.g., the skull base).³²

Most types of mesenchymal neoplasms may be found also in the oral region. Benign mesenchymal neoplasms known to occur in the oral cavity include (but are not limited to) hemangiomas, lipomas, schwannomas, neuromas, and neurofibromas. These are relatively rare lesions but should nonetheless be included in the differential diagnosis of intraoral

masses. The diagnosis is usually made on the basis of histopathologic examination of biopsy specimens. Benign bone tumors, although uncommon, are not unknown. Chondromas, hemangiomas, ossifying fibromas, and osteomas may all present as intraoral masses with bony expansion and normal overlying mucosa.

PREMALIGNANT

Leukoplakia

Leukoplakia is defined by the World Health Organization as a whitish patch or plaque that cannot be characterized clinically or pathologically as any other disease and that is not associated with any physical or chemical causative agent (except tobacco).³³ It is therefore a clinicopathologic entity of exclusion. It is often considered a potentially premalignant lesion. Leukoplakic lesions vary in size, shape, and consistency; there is usually no relation between morphologic appearance and histologic diagnosis. Histologic examination may reveal hyperkeratosis, dysplasia, carcinoma in situ (CIS), or invasive squamous cell carcinoma, or other pathologic processes.¹⁶ Dysplasia occurs in as many as 30% of leukoplakic lesions.⁸ Whereas a small percentage of lesions show invasive squamous cell carcinoma on pathologic examination,¹⁴ 60% of oral mucosa carcinomas present as white, keratotic lesions.¹⁶

Because leukoplakias are clinicopathologic entities, a biopsy result of “hyperkeratosis, acanthosis with or without inflammation” must be further interpreted by the clinician as to whether the clinical lesion could represent a frictional injury such as morsicatio mucosae oris, benign alveolar ridge keratosis, or some other less well-defined frictional keratosis. This is because it is well known that some so-called “benign leukoplakias” will develop squamous cell carcinoma when followed. Furthermore, the entity “proliferative verrucous leukoplakia” almost always shows benign histology for many years and the majority if not all of such lesions become invasive cancer when followed over time.

All leukoplakic lesions should undergo biopsy. For small areas of leukoplakia, excisional biopsy is usually appropriate. For larger lesions, incisional biopsy is generally preferable: it is important to obtain an adequate-size biopsy specimen in that varying degrees of hyperplasia and dysplasia may occur within the same specimen. There is no consensus regarding the management of “nondysplastic” leukoplakias that in the clinician’s opinion are not reactive or inflammatory in nature. Some believe that such hyperkeratotic lesions should be followed on a long-term basis, with rebiopsy performed if there are any changes in size or appearance. Others believe that they should be narrowly excised and, if the lesion recurs, more widely excised. Lesions characterized by dysplasia and CIS should be completely excised to clear margins when possible.

Erythroplakia

Erythroplakia is defined as a red or erythematous patch of the oral mucosa. It is associated with significantly higher rates of dysplasia, CIS, and invasive carcinoma than leukoplakia is.⁸ Erythroplakia is managed in much the same fashion as

leukoplakia, with biopsy performed to rule out a malignant or premalignant lesion. Complete surgical excision is indicated if either a malignancy or a premalignancy is confirmed, and frequent follow-up is necessary.

MALIGNANT

Minor Salivary Gland Malignancies

The majority (60 to 70%) of minor salivary gland neoplasms are malignant, with adenoid cystic carcinoma, mucoepidermoid carcinoma, and adenocarcinoma [see Figure 6a] being the most commonly encountered cancers.^{26,34} As with benign minor salivary gland neoplasms, the hard and soft palates are the most common sites.³⁴

A minor salivary gland malignancy usually appears as a painless, slow-growing, intraoral mass.³⁵ Nodal involvement at presentation is uncommon.²⁶ Treatment usually involves surgical excision; adequate margins should be obtained with frozen-section control. Because these malignancies—particularly adenoid cystic carcinoma and polymorphous low-grade adenocarcinoma—have a propensity for perineural spread, frozen-section analysis of the nerves within the field of resection is usually obtained at the time of operation. If perineural spread occurs, postoperative irradiation is usually indicated, and distant metastases are likely to develop despite surgery and locoregional radiotherapy. As a result, it is usually best to limit the extent of the operation if major morbidity is anticipated from a radical resection.

Neck dissection is warranted in the treatment of minor salivary gland malignancies only if there is clinical or radiographic evidence of cervical metastases. Postoperative irradiation is indicated for most patients with high-grade malignancies, positive or close surgical margins, cervical metastases, or pathologic evidence of perineural spread or bone invasion.³⁵ Studies suggest that postoperative radiotherapy allows improved local control and may lead to longer disease-free survival.^{36,37}

Local recurrence and distant metastases are common, often developing many years later; regional recurrence is uncommon.³⁴ The survival rate for adenoid cystic carcinoma is relatively high (approximately 80%) at 5 years but decreases dramatically over the subsequent 10 to 15 years.^{34,38} Various factors predictive of poor survival have been identified [see Table 5].³⁸

Mucosal Melanoma

After the sinonasal region, the oral cavity is the site at which mucosal melanoma most often occurs in the head and neck.³⁹ Within the oral cavity, mucosal melanoma is most frequently found involving the upper alveolus and the hard palate.⁴⁰ It is most common in men, usually developing in the sixth decade of life.⁴⁰ No specific risk factors or premalignant lesions have been identified. There may, however, be an increased risk among certain subsets of East Asian patients.

Oral mucosal melanoma typically appears as a flat or nodular pigmented lesion, frequently associated with ulceration. Amelanotic melanoma is, fortunately, rare.⁴¹ Patients usually seek medical attention at an advanced stage of the

Figure 6 Shown are malignant lesions of the oral cavity: (a) polymorphous low-grade adenocarcinoma of the hard palate (raised, erythematous lesion); (b) extensive squamous cell carcinoma of the tongue, the alveolar ridge, and the floor of the mouth; (c) squamous cell carcinoma of the right floor of the mouth, with mandibular invasion on computed tomography scan; (d) squamous cell carcinoma of the lip (ulcerative lesion); (e) squamous cell carcinoma of the floor of the mouth (exophytic lesion); (f) squamous cell carcinoma of the hard palate; and (g) squamous cell carcinoma of the retromolar trigone.

disease, when pain develops or when they notice a change in the fit of their dentures. Early asymptomatic lesions are usually identified incidentally by either a physician or a dentist. Approximately 25% of patients have nodal metastases at presentation.⁴⁰ Tumors thicker than 5 mm are associated with an increased likelihood of nodal metastases at presentation.⁴²

No formal staging system has been developed for mucosal melanoma. The diagnosis is made by means of biopsy and

immunohistochemical staining (e.g., for HMB-45 antigen, Melan-A, or S-100 protein). Any suspicious pigmented lesion in the oral cavity should undergo biopsy to rule out melanoma. Amalgam tattoos are common in the oral cavity and can often be diagnosed on the basis of the presence of metallic fragments on dental radiographs.

Mucosal melanoma is managed primarily with surgical resection. The role of radiation therapy in this setting remains controversial.³⁹ Some clinicians recommend postoperative radiotherapy for all cases of mucosal melanoma; others recommend it only for patients with close or positive margins. The role of lymph node mapping has not been defined for mucosal melanoma. Because of the high incidence of nodes at presentation and the high regional recurrence rates reported in some studies, consideration should be given to treating the neck prophylactically by extending the postoperative radiation fields to cover this region.^{39,40}

The poor prognosis of mucosal melanoma with conventional treatment employing surgery and irradiation is a strong argument for referring patients to a medical oncologist for

Table 5 Poor Prognostic Factors for Minor Salivary Gland Malignancies

Positive margins
Male sex

potential enrolment in postoperative systemic therapy trials. The survival rate for oral mucosal melanomas at 5 years ranges from 15 to 45%,^{40,41,43} with most patients dying of distant disease. Nodal involvement further reduces survival.⁴¹ Melanoma of the gingiva has a slightly better prognosis than melanoma of the palate.⁴¹ Several factors predictive of poor survival have been identified [see Table 6].⁴⁰ The relation between lesion depth and prognosis is not as clearly defined for oral mucosal melanoma as it is for cutaneous melanoma.

Squamous Cell Carcinoma

The incidence of squamous cell carcinoma increases with age, with the median age at diagnosis falling in the seventh decade of life,^{44,45} and is higher in men than in women. This cancer may be found at any of a number of oral cavity sub-sites [see Figure 6, *b through g*]. Lip carcinoma is the most common oral cavity cancer; 80 to 90% of these lesions occur on the lower lip.¹³ After the lip, the most common sites for oral cavity carcinoma are the tongue and the floor of the mouth. When the primary lesion is on the tongue, the lateral border is the most common location, followed by the anterior tongue and the dorsum.⁸ Approximately 75% of cases of oral cavity squamous cell carcinoma arise from a specific 10% of the mucosal surface of the mouth,¹¹ an area extending from the anterior floor of the mouth along the gingivobuccal sulcus and the lateral border to the retromolar trigone and the anterior tonsillar pillar.¹¹ Verrucous carcinoma is a subtype of squamous cell carcinoma and occurs most frequently on the buccal mucosa, appearing as a papillary mass with keratinization.

Between 80 and 90% of patients with oral cavity carcinoma have a history of either tobacco use (cigarette smoking or tobacco chewing) or excessive alcohol intake.⁴⁶ A synergistic effect is created when alcohol and tobacco are frequently used together.⁴⁶ In Asia, the practice of reverse smoking is associated with a high incidence of palatal carcinoma; betel nut chewing is associated with a high incidence of buccal carcinoma. The incidence of tumors in patients who have never smoked or drunk alcohol is rising, and the role of human papillomavirus in the pathogenesis and prognosis of this disease continues to be defined.⁴⁷

Small lesions tend to be asymptomatic. Larger lesions are often associated with pain, bleeding, poor denture fit, facial weakness or sensory changes, dysphagia, odynophagia, and trismus. Oral intake may worsen the pain, leading to malnutrition and dehydration.

Squamous cell carcinoma of the oral cavity has four different possible growth patterns: ulceroinfiltrative, exophytic, endophytic, and superficial [see Table 7].⁴⁸ Lip and buccal carcinomas tend to appear as exophytic masses. Ulceration is less common early in the course of cancers arising at these sites, but it may develop as the lesion enlarges. Cancers of the floor of the mouth may be associated with invasion of the

Table 7 Growth Patterns of Squamous Cell Carcinoma of Oral Cavity⁴⁸

Growth Pattern	Characteristics
Ulceroinfiltrative	Most common pattern; appears as ulcerated lesion that penetrates deep into underlying structures with surrounding induration
Exophytic	Common on lip and buccal mucosa; appears as papillary mass that may ulcerate when large
Endophytic	Uncommon; extends deep into soft tissue, with only small surface area involved
Superficial	Flat, superficial appearance; may be either a white patch or a red/velvety patch

tongue and the mandible. Decreased tongue mobility as a result of fixation is an indicator of an advanced tumor.^{48,49} Mandibular invasion occurs frequently in carcinomas of the floor of the mouth, the retromolar trigone, and the alveolar ridge as a consequence of the tight adherence of the mucosa to the periosteum in these regions. The risk of mandibular invasion increases with higher tumor stages. The majority (70 to 80%) of alveolar ridge carcinomas occur on the lower alveolus, often in areas of leukoplakia.⁵⁰

Oral cavity carcinoma is generally classified according to the staging system developed by the American Joint Committee on Cancer [see Table 8 and Table 9].⁵¹ Staging is based on clinical examination and diagnostic imaging. The diagnosis is made on the basis of biopsy and immunohistochemical staining (e.g., for cytokeratin and epithelial membrane antigen).

Squamous cell carcinoma of the oral cavity is usually managed with surgery, radiation therapy, or a combination of the two. Chemotherapy is increasingly used in combination with radiotherapy for patients at high risk of local or regional recurrence. For localized disease without bone invasion, the cure rate for radiation therapy is comparable to that of surgery.⁴⁶ The development of free tissue transfer has allowed for the successful cosmetic and functional reconstruction of large surgical defects of the oral cavity, including the mandible. Advanced tumors of the oral cavity are best managed with both surgery and irradiation. Traditionally, in North America, oral cavity cancer is treated primarily with surgery, and postoperative radiotherapy is added if the disease is advanced or if there are pathologic features indicative of a high risk of recurrence (i.e., positive margins on microscopy, extensive perineural or intravascular invasion, two or more positive nodes or positive nodes at multiple levels, or nodal capsular extension). North American practice is reflected in the guidelines developed by the American Head and Neck Society (www.headandneckcancer.org/clinicalresources/docs/oralcavity.php).

Radiation may be delivered to an oral cavity carcinoma via either external beam radiotherapy or brachytherapy, with the former being more commonly employed. Postoperative radiation, if indicated, should be started 4 to 6 weeks after surgery. The total radiation dose depends on the clinical and pathologic findings; the usual range is between 50 and 70 Gy, administered over 5 to 8 weeks. Primary radiation therapy is indicated for patients with stage I and selected stage II oral

Table 6 Poor Prognostic Factors for Mucosal Melanoma

Amelanotic melanoma
Advanced stage at presentation
Tumor thickness > 5 mm
Presence of vascular invasion
Distant metastases

Table 8 American Joint Committee on Cancer TNM Classification of Head and Neck Cancer

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor 2 cm or less in greatest dimension
	T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
	T3	Tumor more than 4 cm in greatest dimension
	T4a	Tumor invades adjacent structures, extending through cortical bone into deep (extrinsic) muscles of tongue, maxillary sinus, or facial skin
Regional lymph nodes (N)	T4b	Tumor invades masticator space, pterygoid plates, or skull base or encases internal carotid artery
	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastases
	N1	Metastases in a single ipsilateral lymph node ≤ 3 cm in greatest dimension
	N2a	Metastases in a single ipsilateral lymph node > 3 cm but ≤ 6 cm in greatest dimension
	N2b	Metastases in multiple ipsilateral lymph nodes, none > 6 cm in greatest dimension
	N2c	Metastases in bilateral or contralateral lymph nodes, none > 6 cm in greatest dimension
Distant metastases (M)	N3	Metastases in lymph node > 6 cm in greatest dimension
	MX	Distant metastases cannot be assessed
	M0	No distant metastases
	M1	Distant metastases

cavity carcinomas, patients who refuse surgery or in whom surgery is contraindicated, and patients with incurable lesions who require palliative treatment. Radiation therapy is less effective against large or deeply invasive tumors, especially those that are invading bone, and therefore generally is not used alone for curative management of T3 and T4 lesions. For advanced-stage tumors of the oral cavity, surgery with postoperative radiotherapy is performed to decrease recurrence rates. Brachytherapy can be used as an adjunct when close or positive margins are noted. Brachytherapy also has a role in the management of recurrence or previously irradiated patients.⁵²

The decision regarding which treatment is presented to a patient as the first option is often determined by factors other than the extent of the tumor. Patient factors to be considered include desires and wishes, age, medical comorbidities, and performance status. Disease factors to be considered include tumor grade and stage, extent of invasion, primary site, the presence and degree of nodal or distant metastasis, and previous treatment. It is often helpful to discuss each case at a multidisciplinary treatment planning conference to develop a ranked list of options.

Squamous cell carcinoma of the oral cavity tends to spread to regional lymph nodes in a relatively predictable fashion. The primary levels of metastatic spread from oral cavity carcinoma include level I through III nodes and, less frequently, level IV nodes^{53–55}; metastases to level V are infrequent.^{53,55} The likelihood that cervical node metastases will develop varies depending on the location of the primary tumor in the oral cavity and on the stage of the tumor. Cervical metastases from carcinomas of the lip or the hard palate usually occur only in advanced disease⁸; however, cervical metastases from carcinomas of any of the other oral cavity subsites are common at presentation [see Table 10].^{8,11,48,50,51,53,56,57} Larger tumors carry a higher risk of cervical metastasis.

The clinically positive neck is usually managed with either a radical or a modified radical neck dissection, depending on the extent of the disease. Some studies have found that for N1 and some N2a patients, a comparable control rate can be achieved with a selective neck dissection encompassing levels I through IV, with postoperative radiation therapy added when indicated.^{58,59}

The clinically negative neck can occasionally be managed with observation alone, with treatment initiated only when nodal metastases develop. Alternatively, the nodal basins at risk can be managed prophylactically by means of either surgery or radiation therapy (involving levels I through III and, possibly, IV). The rationale for prophylactic neck management is that treatment initiated while metastases are still

Table 9 American Joint Committee on Cancer Staging System for Head and Neck Cancer

Table 10 Incidence of Nodal Metastases* at Presentation in Oral Cavity Subsites

Oral Cavity Subsite	Incidence of Metastases (%)
Lip	10
Tongue	30–40
Floor of the mouth	50
Alveoli	28–32
Buccal mucosa	40–52

*Clinically detectable or occult.

occult is thought to be more effective than treatment initiated after the disease has progressed to the point where it is clinically detectable. For this reason, many clinicians advocate prophylactic neck dissection for patients with oral cavity carcinomas who are at moderate (15–20%) risk for occult metastases at presentation. The selective neck dissection not only addresses any occult metastatic nodes but also functions as a staging procedure that helps in determining the prognosis and assessing the need for postoperative radiotherapy.^{60,61} In general, elective neck management is recommended for T2 and higher-stage carcinomas of the tongue, the floor of the mouth, the buccal mucosa, the alveolus, and the retromolar trigone, as well as for advanced (T3 or T4) carcinomas of the lip and the hard palate.^{8,11,48,56,57,62,63} Most surgeons now emphasize the depth of invasion of the primary tumor as a critical determinant of the risk of occult nodal metastases. It has been suggested that elective treatment of the neck with surgery or radiation therapy should be considered on the basis of the depth of tumor invasion rather than the surface diameter of the lesion. The tumor depth that is held to warrant investigation varies among published studies, ranging from 2 to 5 mm.^{64–66} Bilateral neck dissection may be indicated for midline oral cavity cancers.

The prognosis depends on the location of the tumor in the oral cavity. Overall, if all of the oral cavity subsites are considered together, the presence of cervical metastases decreases survival by approximately 50%. Varying 5-year survival rates have been reported for the different subsites of the oral cavity [see Table 11].^{8,11,48,50,51,56,67}

Oral Cavity Manifestations of HIV Infection

Infectious and neoplastic oral cavity lesions are often the first manifestation of HIV infection or the first indication of the progression to AIDS.

INFECTIONS

The same organisms that affect the general population cause most of the oral infections seen in the HIV population; however, oral infections in HIV patients tend to be recurrent, comparatively severe, and relatively resistant to treatment.⁶⁸ Oral hairy leukoplakia, caused by Epstein-Barr virus, is a

common oral infection seen almost exclusively in the HIV population. It presents as an asymptomatic, corrugated, whitish, nonremovable, slightly raised patch on the lateral borders of the tongue. The finding of such a lesion on clinical examination of an HIV patient is suggestive of the diagnosis, but confirmation of the diagnosis requires biopsy. Treatment usually is not necessary. High-dose acyclovir may be given if the patient requests treatment.

Several rare infections of the oral cavity are being seen with increasing frequency in the HIV population, including tuberculosis, syphilis, *Rochalimaea henselae* infection (bacillary angiomatosis), *Borrelia vincentii* infection (acute necrotizing ulcerative gingivitis), cryptococcosis, histoplasmosis, coccidioidomycosis [see Figure 7], and human papillomavirus infection.

NEOPLASMS

The two most common intraoral neoplasms in the HIV population are Kaposi sarcoma and non-Hodgkin lymphoma. Kaposi sarcoma occurs most commonly in patients with HIV, although it is not exclusive to this population. It frequently involves the oral cavity, showing a predilection for the attached mucosa of the palate or the gingiva.⁶⁸ The characteristic lesions are blue, brown, purple, or red exophytic masses that may be either confined to the oral mucosa or systemic. They are usually asymptomatic but may become painful or obstructive with growth or ulceration. Treatment is aimed at palliation of symptoms and may involve sclerotherapy, intralesional chemotherapy, laser ablation, cryotherapy, surgical excision, or radiation therapy.⁶⁹ Systemic chemotherapy may be provided if the disease is systemic.

Figure 7 Shown is coccidioidomycosis of the tongue in an HIV-positive patient.

The risk of non-Hodgkin lymphoma is much higher in the HIV population than in the general population.⁶⁹ It should be suspected in any HIV patient who presents with an intraoral mass or an ulcerated lesion. Non-Hodgkin lymphoma appears as painful lesions that show a predilection for the palate, the retromolar trigone, and the tongue. Associated symptoms include facial paresthesias, loose dentition, fever, night sweats, and weight loss. Local disease is managed with radiation; systemic disease is managed with chemotherapy.

Financial Disclosures: None Reported.

Table 11 Five-Year Carcinoma Survival Rates for Oral Cavity Subsites

Oral Cavity Subsite	Survival Rate
Lip	80%; > 90% for early-stage disease
Tongue	30–35% (advanced-stage disease); > 80% (early-stage disease)
Floor of the mouth	85% for stages I and II (T1 lesions > 95%); 20–52% for stages III and IV
Alveoli	50–60%
Retromolar trigone	75% for T1 and T2 lesions; approximately 20–50% for T3 and T4 lesions
Buccal mucosa	49–68%
Palate	85% for T1 lesions; 30% for T4 lesions

2 PAROTID MASS

*Harrison W. Lin, MD, and Neil Bhattacharyya, MD, FACS**

Demographics

Major salivary gland tumors constitute 3 to 6% of all tumors of the head and neck in adults,¹ and approximately 85% of these salivary gland tumors are found in the parotid gland. Roughly 16% of these neoplasms are malignant.² The spectrum of histopathologic entities encompassed by the term “parotid mass” is exceedingly broad and continues to evolve as our understanding of the origin and clinical behavior of the various tumors arising from the parotid gland expands.

Anatomy

The parotid gland is an irregular, wedge-shaped, unilobular salivary gland residing in the parotid space, a compartment that additionally contains the facial nerve (cranial nerve VII), sensory and autonomic nerves, branches of the external carotid artery and external jugular vein, and lymphovascularity [see *Figure 1*].³ The gland itself resides within the split layers of the superficial layer of the deep cervical fascia and overlies the upper one fourth of the sternocleidomastoid muscle, the ramus of the mandible, and the masseter muscle. Approximately 20% of the gland extends medially through the stylomandibular tunnel, which is formed by the posterior edge of the mandibular ramus, the anterior border of the sternocleidomastoid muscle, and the posterior belly of the digastric muscle. At its lower pole, the parotid gland is separated from the submandibular gland by the stylomandibular ligament, which extends from the tip of the styloid process to the angle and the posterior edge of the mandible.

The seventh cranial nerve artificially divides the parotid gland into two surgical zones: tissue lateral to the facial nerve is designated as the superficial lobe, whereas the medial portion is referred to as the deep lobe. Moreover, each lobe has been described to have variable processes, including the condylar, meatal, and posterior processes of the superficial lobe and the glenoid and stylomandibular processes of the deep lobe. Furthermore, a retromandibular portion of the deep lobe resides in the prestyloid compartment of the parapharyngeal space, anterior to the styloid process and associated musculature, the carotid sheath, and cranial nerves IX through XII. Note that the separation of the parotid gland into superficial and deep lobes is not based on a fascial plane. The parotid isthmus, the portion of the gland between the ramus of the mandible and the posterior belly of the digastric muscle, connects the superficial with the deep lobes of the parotid gland.

The parotid (Stensen) duct originates from the superficial lobe of the gland, courses anteriorly on the lateral surface of

the masseter muscle, and then turns medially to pierce the buccinator muscle at the level of the second maxillary molar tooth and open into the mouth through the parotid papilla. The expected course of the duct is approximated by a line drawn between the tragus and philtrum of the upper lip, midway between the angle of the mouth and the zygomatic arch.

Etiology

Two predominant theories of the neoplastic pathogenesis of parotid masses have been proposed, including the bicellular and multicellular theories. The former, also referred to as the reserve cell theory, suggests that tumors arise from stem cell populations in both the excretory and intercalated ductal systems. Warthin tumor, mixed tumor, oncocytoma, acinic cell carcinoma, adenoid cystic carcinoma, and oncocytic carcinoma are proposed to arise from stem cells of the intercalated duct, whereas squamous cell carcinoma (SCC) and mucoepidermoid carcinoma are thought to derive from excretory duct stem cells. Alternatively, the multicellular theory suggests that the various parotid tumors arise from the fully differentiated cells within the salivary gland unit. Based on this theory, mucoepidermoid and squamous cell carcinomas derive from excretory duct cells, oncocytic tumors from striated duct cells, acinous tumors from acinar cells, and mixed tumors from intercalated duct cells and myoepithelial cells.⁴

Although the true nature of the neoplastic transformation of parotid gland cells is yet to be fully elucidated, these and other classification systems are founded on the understanding that primary parotid tumors are of epithelial origin. The parotid gland also hosts numerous lymph nodes that serve as a basin for metastatic spread of malignancies of the head. Accordingly, parotid masses will not infrequently represent the presenting sign of a cutaneous SCC or melanoma of the temple or scalp, for example.

Differential Diagnosis

NONNEOPLASTIC CONDITIONS

The causes of nonneoplastic parotid masses include congenital, infectious or inflammatory, and lymphoepithelial conditions. Congenital lesions such as hemangiomas and vascular malformations often present in childhood as a swelling in the preauricular region. First branchial cleft cysts can also present in the pediatric population and can be manifest as a mass inferior to the cartilaginous external auditory canal and with a cyst tract that will have a variable relationship with the branches of the facial nerve.

Inflammatory disorders of the parotid gland can be categorized into acute and chronic processes. Moreover, acute infections of the salivary glands can be further subclassified

* The authors and editors gratefully acknowledge the contributions of the previous author, Ashok R. Shaha, MD, FACS, to the development and writing of this chapter.

Figure 1 Anatomy of the parotid region. Branches of the facial nerve: A = temporal; B = zygomatic; C = buccal; D = marginal; E = cervical.

into viral and bacterial processes. Although viral parotid infections by the RNA virus paramyxovirus resulting in the mumps syndrome are now exceedingly rare following the introduction of the mumps vaccine in 1967, acute viral parotitis from the influenza, parainfluenza, adenovirus, cytomegalovirus, coxsackievirus, and enteric cytopathic human orphan (ECHO) viruses have been reported in the literature.⁵ Acute bacterial infections of the parotid gland, however, are by far more common and are believed to be the result of retrograde contamination of the salivary ducts and parenchymal tissues by oral flora combined with stasis of salivary flow, often attributable to dehydration. Additionally, the serous composition of the saliva produced by the parotid gland lacks

many of the antibacterial lysosomes, antibodies, and mucins found in the mucinous saliva produced by the other major salivary glands. Accordingly, bacterial sialadenitis most commonly affects the parotid gland. Relatively sudden onset of pain, tenderness, and swelling of the parotid are the most frequent presenting signs and symptoms, and treatment consists of hydration, sialogogues, and systemic antimicrobial therapy. If a discrete abscess is suspected and identified on cross-sectional imaging, surgical or radiologically guided needle drainage may be required.

Chronic inflammatory disorders of the parotid gland are frequently manifested by a mildly painful, recurrent, and gradual enlargement of the gland. Of these disorders, chronic

sialadenitis is the most frequently encountered and is believed to be the result of reduced rates of salivary production and flow, resulting in frequent subacute suppurative infections, sialectasis, ductal ectasia, and progressive acinar cell loss. Initial treatment is similar to that of acute bacterial sialadenitis, and failure to respond to conservative measures may prompt consideration for surgical interventions, including ductal dilation, ductal ligation, and parotidectomy. In sarcoidosis, salivary gland involvement may cause duct obstruction, pain associated with the duct, xerostomia, or enlargement of the gland. The diagnosis is supported by chest films that show bilateral hilar adenopathy and by elevated levels of angiotensin-converting enzyme. Uveoparotid fever (Heerfordt disease), a subtype of sarcoidosis manifested by the triad of uveitis, parotid enlargement, and facial weakness, can persist for months to years and will often resolve spontaneously and without treatment.⁶

Lymphoepithelial lesions of the parotid gland may be divided into lymphocytic infiltrative diseases and lymphomas. In many cases, patients with lymphocytic infiltrative diseases such as Mikulicz disease, sicca complex, and Sjögren syndrome have had their conditions for long periods and simply believe that their chronic enlargement of bilateral parotid glands was normal facial soft tissue changes associated with age. Eighty percent of patients with primary Sjögren syndrome will experience parotid gland swelling; moreover, malignant transformation to high-grade lymphoma is known to occur. Lymphoepithelial cysts are benign cystic lesions that may arise from lymph nodes or from lymphoid aggregates in the salivary gland. These lesions may be associated with HIV infection.

Primary lymphoma of the salivary gland is uncommon, occurring in fewer than 5% of patients with parotid masses. Suggestive clinical features include (1) the development of a parotid mass in a patient with a known history of malignant lymphoma, (2) the occurrence of a parotid mass in a patient with an immune disorder (e.g., Sjögren syndrome, rheumatoid arthritis, or AIDS), (3) the presence of a parotid mass in a patient with a previous diagnosis of benign lymphoepithelial lesion, (4) the finding of multiple masses in one parotid gland or of masses in both parotid glands, and (5) the association of a parotid mass with multiple enlarged cervical lymph nodes unilaterally or bilaterally.⁷

As discussed, infectious or inflammatory diseases involving the parotid, unlike neoplasms, tend to give rise to pain in their early stages. However, certain parotid malignancies may also present with pain attributable to sensory nerve involvement. Most such inflammatory conditions begin with diffuse enlargement of one or more salivary glands rather than with presentation with a discrete, palpable parotid mass. Although parotitis is generally unilateral, it may be bilateral or affect other salivary glands if a systemic causative condition is involved. The pain reported may be related to the presence of a stone in the salivary duct or to diffuse obstructive parotitis. Chronic parotitis may lead to recurrent infection and inflammation. When recurrent swelling of the salivary gland does occur, it may be directly related to eating and increased salivation.

NEOPLASTIC CONDITIONS

Neoplastic masses may be present for years without causing any symptoms and affect both men and women at similar

rates. Benign salivary tumors tend to be more common in younger persons, whereas malignant parotid lesions are more common in the fifth and sixth decades of life.⁸ The classic presentation of a benign parotid tumor is that of an asymptomatic parotid mass that has been present for months to years, often exhibiting slow growth.

Benign Neoplasms

Benign neoplasms of the parotid, which include pleomorphic adenoma, basal cell adenoma, myoepithelioma, Warthin tumor, oncocytoma, and cystadenoma, are typically slow-growing and rarely exhibit malignant transformation. However, the observation of rapid growth in a long-standing pleomorphic adenoma (often 10 to 15 years later) is suggestive of malignant transformation. In a 2005 study of 94 patients with pleomorphic adenoma, malignant transformation to carcinoma ex pleomorphic adenoma was documented in 8.5% of cases.⁹ Rapid tumor growth, metastasis to lymph nodes, deep fixation, and facial nerve weakness are all strongly suggestive of malignant disease and are indicators of a poor prognosis.¹⁰ Although pain is more often experienced by patients with inflammatory or infectious conditions, it is also reported by some patients with infiltrative malignant tumors. In these patients, pain is another indicator of a poor prognosis.^{11,12}

Malignant Neoplasms

Although considerable debate continues to surround the histopathologic classification of malignant parotid tumors, most clinicians currently prefer the classification system of the Armed Forces Institute of Pathology¹³ or that of the World Health Organization.¹⁴ Malignant parotid neoplasms include primary SCC, mucoepidermoid carcinoma, acinic cell carcinoma, adenocarcinoma, adenoid cystic carcinoma, carcinoma ex pleomorphic adenoma, and malignant mixed tumor. The presence of facial nerve palsy should raise the index of suspicion for malignancy. Occasionally, patients present with classic Bell palsy. This condition is usually of viral origin, and most patients recover over time. If Bell palsy persists, however, further investigation is required, including imaging or biopsy studies to rule out an associated parotid lesion.¹⁵

Mucoepidermoid carcinoma is the most common malignant tumor of the parotid gland, comprising roughly one third of all parotid cancers, and is subclassified into low-, intermediate-, and high-grade tumors. For high-grade tumors, selective cervical node dissection may be indicated and postoperative radiation therapy is often required. Combined surgical and radiation therapies for such tumors results in a 5-year survival rate of under 50%. In contrast, low-grade tumors are more circumscribed and contain more mucinous cells. Surgical therapy without radiation yields a 5-year survival rate of 75%.

Adenoid cystic carcinoma is an aggressive salivary gland tumor that exhibits a very high incidence of perineural spread with skip metastasis along the facial nerve and its branches, and the incidence rises with higher tumor stages.¹⁶ The incidence of local recurrence is also very high; therefore, postoperative radiation therapy should be provided to patients who are at high risk for relapse, such as those with close or positive margins and those with perineural invasion. Although

Approach to Evaluation of a Parotid Mass

the incidence of cervical lymph node metastasis in patients with adenoid cystic carcinoma is relatively low, the incidence of distant metastasis (especially pulmonary metastasis) has been reported to be as high as 38%.¹⁷ Long-term follow-up in these patients is essential.

Adenocarcinoma has been considered a shrinking category as advances in electron microscopy and immunohistochemistry have reclassified many of these tumor variants into other subtypes and histopathologies. Adenocarcinomas are exceedingly aggressive tumors with high rates of facial nerve involvement, regional disease, and distant metastases and, accordingly, should be managed as a high-grade parotid tumor with surgical and radiation therapies.

Acinic cell carcinoma is a low-grade tumor with a female predominance and bilateral presentation approximately 3% of the time. Tumors are frequently well circumscribed, but a small percentage of patients will present with cervical nodal metastases. Patients with acinic cell carcinoma are typically managed with surgical therapy alone, although histopathologic findings to suggest a more aggressive, high-grade tumor have been proposed to serve as indicators for postoperative radiation therapy.¹⁸

Primary SCC of the parotid gland is quite rare, and most diagnoses of parotid SCC represent skin cancer that has metastasized to the periparotid lymph nodes. Primary SCC has a high malignant potential, and radical surgical extirpation (with preservation of the facial nerve when possible), followed by planned postoperative radiotherapy, is the treatment of choice.¹⁹

Metastatic Neoplasms to the Parotid

The parotid gland represents the first or second nodal basin for metastatic scalp, temple, and auricular cutaneous malignancies. Although the incidence of metastatic parotid disease is comparatively low in the Northern Hemisphere, it has been reported to be far more common than primary parotid disease in regions of the world with high rates of skin cancers, such as Australia.²⁰ Cutaneous SCC and melanoma are by far the most frequently encountered metastatic parotid malignancies and, despite treatment, will exhibit local or distant failure in 25 to 50% of cases. Other cancers that have been reported to metastasize to the parotid include basal cell, Merkel cell, and small cell carcinomas.

Presentation and Diagnostic Workup

HISTORY

Evaluation of any parotid mass should begin with a detailed clinical history. Comprehensive inquiries regarding the duration of signs and symptoms are paramount as masses resulting in local pain and swelling of recent onset (i.e., within the past few days) are more likely to be infectious or obstructive in nature. If the mass has been present for a longer period (i.e., weeks to months), a neoplasm is more likely. Unfortunately, the

presentations of some nonneoplastic conditions resemble those of neoplasms, and distinguishing one type of condition from the other can be challenging. Accordingly, the history should continue with further questions focusing on local or systemic signs and symptoms, the presence of swelling or other masses in the salivary glands, and previous medical conditions, including cancers of the skin.

PHYSICAL EXAMINATION

The physical examination begins with an assessment of the extent of the disease in the parotid region, the neck, and the parapharynx. Extension of a tumor to regional compartments can be manifest as trismus or as motor or sensory deficits resulting from neural invasion. Palpation of the mass will reveal whether it is painless or painful; soft, firm, hard, or cystic; and mobile or fixed to deep tissue or skin. The skin of the scalp, ear, and face should be carefully examined for suspicious lesions, and the neck is palpated for adenopathy. In the oral cavity, the Stensen ducts are examined for discharge or saliva with parotid massage. The oropharynx is examined for asymmetries or lateral wall deviation.

The most common presentation of a parotid mass, whether benign or malignant, is an asymptomatic swelling in the preauricular or retromandibular region. Of note, the location of the parotid mass is a very important diagnostic factor. A benign tumor will classically present as a firm, mobile, and marblelike mass in the superficial portion of the gland and not fixed to the deeper structures or to the skin. Parotid tumors that originate in the deep lobe, however, may present as a vague, diffuse swelling behind the angle of the mandible or as a swelling of the parapharyngeal area, resulting in medial displacement of the tonsil, soft palate, or lateral oropharyngeal wall.

Occasionally, patients will present with metastases to one or more of the 17 to 20 intraparotid or periparotid lymph nodes in the substance of the parotid and along its tail. These lymph nodes may be directly affected by metastatic tumors originating from the anterior scalp or the temporal, periocular, or malar regions. It is critical to obtain a detailed history of any previously excised skin lesions, some of which may have been an SCC or a melanoma primary tumor that metastasized to the periparotid nodes. Generally, such metastasis involves multiple superficial lymph nodes and presents as diffuse enlargement of the parotid parenchyma. With massive involvement of the parotid gland, facial nerve palsy is not uncommon in this setting. Although the majority of metastases to the parotid gland derive from cutaneous SCC or melanoma, metastatic spread from the lung, breast, and kidney has also been reported.

As with any patient with an otolaryngologic complaint, a thorough evaluation of the head and neck, including a detailed visualization of the oral cavity and laryngopharynx, is required. Occasionally, a tumor of the oropharynx presents as cervical lymphadenopathy or as metastatic disease in the tail of the parotid. In such cases, it may be difficult to determine whether the patient has a primary salivary gland tumor or a metastatic lesion. The presence of any suspicious pathologic condition in the oropharynx or the base of the tongue is an indication for appropriate endoscopy and biopsy of the suspected primary site.

Physical findings suggestive of malignancy include a large and fixed mass, facial nerve weakness, lymph node metastasis, and skin involvement; patients with advanced parotid malignancies may present with trismus. Although patients with benign parotid tumors rarely exhibit facial nerve weakness, approximately 12 to 15% of patients with parotid malignancies have facial nerve dysfunction at presentation. The most common causes of facial nerve weakness in this setting are adenoid cystic carcinoma, poorly differentiated carcinoma, and SCC.

The presence of cervical lymph node metastasis may direct the clinician’s attention to the parotid mass, although less than 20% of persons with parotid malignancies actually have clinically apparent cervical lymph node metastases at the time of the initial presentation.^{11,21} The parotid tumors most commonly associated with metastatic disease to the lymph nodes at presentation are undifferentiated carcinoma (89%),²² high-grade mucoepidermoid carcinoma (42%),²³ and SCC (44%).²⁴ Lymph node metastases may also derive from high-grade adenocarcinomas (22%) or malignant mixed tumors (16%).²⁵

Some patients will present without any symptoms, with the only significant physical examination finding being an oropharyngeal mass, which is suggestive of either a deep-lobe parotid or parapharyngeal tumor. Given that between 80 and 90% of the parotid tissue is superficial to the facial nerve, the majority of parotid tumors, not surprisingly, develop within the superficial lobe of the parotid. However, approximately 10% of parotid masses will be found within the deep lobe. Most deep-lobe parotid tumors are benign, in which case, surgical treatment generally consists of a superficial parotidectomy with dissection and preservation of the facial nerve, followed by removal of the tumor. Occasionally, however, malignant deep-lobe parotid tumors do occur, and such tumors frequently involve the facial nerve. Surgical treatment may require sacrifice of the facial nerve in select circumstances. Most patients who have undergone surgical treatment of a malignant deep-lobe tumor will require postoperative radiation therapy.

FINE-NEEDLE ASPIRATION CYTOLOGY

Although fine-needle aspiration cytology (FNAC) has been shown to play a vital part in the management of head and neck SCC, the role of FNAC in parotid gland masses has yet to be fully resolved. This is attributable in large part to the perceived minimal impact of FNAC results on therapeutic decision making as most parotid masses, both benign and malignant, will require surgical excision and thereby provide a definitive pathologic diagnosis. Moreover, the variability of histopathologic subtypes, intralesional cellular distribution, and cytopathologist expertise has led some surgeons to question the utility of preoperative FNAC.

However, the ability of FNAC to distinguish masses of benign nature from those of malignant nature, salivary gland origin from those of nonsalivary gland origin (e.g., sarcoma, lymphoma, metastatic melanoma), and, in some cases, low-grade malignancy from high-grade malignancy has been suggested to provide useful guidance for medical and surgical planning [see Table 1]. Preoperative discovery of a non-salivary gland neoplasm in a parotid mass may preclude surgical excision in lieu of medical, radiation, or palliative

therapies. Additionally, preoperative knowledge of a parotid malignancy has been shown to significantly impact both surgical planning and surgical results. In one study, patients who underwent parotidectomy for an FNAC-diagnosed parotid malignancy had significantly higher rates of both upfront cervical neck dissections and clear pathologic margins.²⁶ In addition, knowledge of the nature of a parotid mass may greatly influence patient counseling, which may have particular utility in patients who are poor surgical candidates or prefer a watchful-waiting strategy, when appropriate. Accordingly, the use of FNAC in the evaluation of a parotid mass should be strongly considered as it is generally felt to be an excellent investigational tool as long as it is employed in the appropriate clinical context.

IMAGING

Modern imaging of salivary gland pathology predominantly consists of computed tomography (CT) or magnetic resonance imaging (MRI) or both. As with their characteristics in the imaging of other regions of the body,

CT is considered superior to MRI for evaluation of the bony structures, whereas MRI is typically more helpful in soft tissue resolution and in distinguishing between inflammatory conditions and neoplasms. Additionally, MRI may better discern an inferior tail of a parotid mass from an upper cervical mass and detect radiologic signs of malignancy, including irregular, indistinct margins with parotid tissue, low signal intensities on all imaging sequences, and tumor infiltration into muscle, bone, or nerve [see Figure 2].

Figure 2 Axial (a) T₁ and (b) T₂ magnetic resonance images of a left superficial parotid pleomorphic adenoma demonstrating the classic irregular, bosselated appearance.

Similar to FNAC, the utility of the various imaging modalities used in the evaluation of a parotid mass continues to be controversial. Many surgeons believe that preoperative ultrasonography, CT, and MRI will provide little to no influence on therapy for a small, mobile, superficial parotid nodule, which would be better assessed with FNAC, surgery, or both. Conversely, management of the more advanced, fixed, aggressive, and deep parotid tumors can be considerably influenced by CT or MRI findings. Patients with diffuse parotid enlargement, tumor extension beyond the superficial lobe, facial nerve weakness, trismus, or deep tumors that are difficult to evaluate clinically should be initially assessed with CT. Fixation to the deeper structures may prompt the need for MRI to evaluate the extent and for parapharyngeal extension or origin. Patients with tumors in close proximity to the facial nerve, external auditory canal, mastoid, mandible, or regional musculature may also benefit from a preoperative MRI, which may influence surgical planning.

Currently, the role of positron emission tomography (PET) in the initial evaluation of a parotid mass remains undefined. This modality may, however, be of some value in the evaluation of suspected recurrent parotid cancers, lymph node metastases, or distant metastases.

Management

BASIC PRINCIPLES

Treatment of a parotid mass depends on the nature and extent of the lesion, which, like most cancers of the body, is categorized and described by a universal staging system. Staging for cancers of the parotid gland is accomplished by means of the familiar tumor-node-metastasis (TNM) system developed by the American Joint Committee on Cancer (AJCC) [see Table 2 and Table 3].

Malignant parotid masses are primarily treated surgically according to established oncologic principles [see Table 4]. An

appropriate parotidectomy with identification and assessment of the facial nerve for tumor involvement is considered the current standard of care. Postoperative radiation therapy is often indicated for more involved and advanced-stage tumors. Moreover, benign parotid masses are frequently managed surgically as well, with exploration of the parotid gland, identification and preservation of the facial nerve, and evaluation of the neoplasm regarded as the customary surgical interventions. Enucleation, once considered an acceptable alternative to superficial parotidectomy for benign pathologies, is now discouraged owing to the possibility of tumor spillage, incomplete removal of the tumor, inadvertent injury to the branches of the facial nerve, and high rates of local recurrence. The need for revision surgery for benign parotid processes is considered unacceptable given the difficulty of surgery on a previously operated tissue bed and consequential increased risk of injury to the facial nerve.

SURGICAL THERAPY

Surgery is the primary treatment modality for nonlymphoid salivary gland neoplasms, both benign and malignant. Optimal surgery for the parotid gland should address both the primary tumor and cervical disease, if present, in a single operation. The minimum surgical intervention for a parotid mass is superficial parotidectomy with identification, dissection, and preservation of the facial nerve, although a subtotal or total parotidectomy and neck dissection may be required for larger tumors that involve the deep lobe of the parotid gland or for patients with clinical or radiologic evidence of regional disease, respectively. If the tumor involves and directly infiltrates the facial nerve, a diagnosis of malignancy, if not previously established preoperatively, should be explored. If a malignant diagnosis is confirmed, a low threshold for nerve sacrifice should be maintained. However, facial nerve preservation despite tumor encroachment on the nerve can be considered as long as all gross disease is removed. With the availability of adjuvant radiation therapy, the surgeon can choose to leave behind microscopic disease, which can be addressed postoperatively. In addition to temporary or permanent facial weakness, patients should be counseled on and consented for other potential complications of parotid surgery, including permanent numbness of the auricle from greater auricular nerve injury and Frey and first-bite syndromes. Frey syndrome, also known as auriculotemporal syndrome or gustatory sweating, is believed to result from misdirected regeneration of cut parasympathetic fibers from the otic ganglion to the parotid gland, leading to the innervation of sweat glands and subcutaneous vasculature. Patients report discomfort, erythema, and perspiration over the parotid bed or neck when eating. First-bite syndrome is a poorly understood complication of surgery in the parapharyngeal space believed to result from injury to the cervical sympathetic chain. A denervation hypersensitivity of parotid myoepithelial cells to parasympathetic neurotransmitters results, leading to supramaximal myoepithelial contraction and consequent pain with the first bite of a meal. Intracutaneous and intraglandular injections of botulinum toxin type A have been shown to provide patients with long-term and effective relief from the symptoms of Frey and first-bite syndromes, respectively.

Table 2 American Joint Committee on Cancer TNM Clinical Classification of Major Salivary Gland Tumors

Primary tumor (T)
TX: Primary tumor cannot be assessed
T0: No evidence of primary tumor
T1: Tumor ≤ 2 cm in greatest dimension without extraparenchymal extension
T2: Tumor > 2 cm but ≤ 4 cm in greatest dimension without extraparenchymal extension
T3: Tumor having extraparenchymal extension without seventh nerve involvement and/or > 4 cm but < 6 cm in greatest dimension
T4a: Tumor invades the skin, mandible, external auditory canal, seventh nerve, and/or > 6 cm in greatest dimension
T4b: Tumor invades the base of skull, pterygoid plates, carotid artery
Regional lymph nodes (N)
NX: Regional lymph nodes cannot be assessed
N0: No regional lymph node metastasis
N1: Metastasis in a single ipsilateral lymph node, ≤ 3 cm in greatest dimension
N2: Metastasis in a single ipsilateral lymph node, > 3 cm but ≤ 6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none > 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none > 6 cm in greatest dimension
N2a: Metastasis in a single ipsilateral lymph node > 3 cm but ≤ 6 cm in greatest dimension
N2b: Metastasis in multiple ipsilateral lymph nodes, none > 6 cm in greatest dimension
N2c: Metastasis in bilateral or contralateral lymph nodes, none > 6 cm in greatest dimension
N3: Metastasis in a lymph node > 6 cm in greatest dimension
Distant metastasis (M)
MX: Distant metastasis cannot be assessed
M0: No distant metastasis
M1: Distant metastasis

An incision in a preauricular skin crease gently curving 2 mm below the auricular lobule and continuing 2 to 3 cm below the mandible is made down to the level of the parotid fascia to prevent lobular distortion and transection of the marginal mandibular branch of the facial nerve, respectively. An anterior flap above the level of the parotid fascia is elevated with a blade or scissors, whereas a posterior flap is raised to expose the tail of the parotid, sternocleidomastoid muscle, and mastoid tip. Dissection then proceeds deeper to

identify the posterior belly of the digastric muscle. Identification of the tragal pointer is then accomplished with cautious dissection along the tragal cartilage, and the main trunk of the facial nerve is typically found roughly 1 cm anterior and deep to this important landmark at the level of the digastric muscle. After the nerve is identified, the superficial lobe of the parotid is removed with the mass with careful dissection along the nerve branches.²⁷ In certain instances, a retrograde approach to facial nerve identification can be used and has been shown to reduce operative time and blood loss and conserve normal parotid tissue without compromising surgical margin status.²⁸

High-grade tumors involving the deep lobe or with extension to the parapharyngeal space may require a total parotidectomy. Following removal of the superficial portion of the gland, the facial nerve and its branches are carefully raised off the deep parotid tissue or tumor, and this tissue is subsequently elevated off the masseter muscle and removed. A cervical-parotid approach with exposure of the internal and external carotid arteries, internal jugular vein, and vagus, spinal accessory, and hypoglossal nerves may facilitate identification and excision of parapharyngeal space masses posterior to the stylomandibular ligament. A midline mandibulotomy to provide additional exposure and control of vessels can also be added for tumors extending to the skull base or encasing the carotid artery. If the tumor extends beyond the parotid gland and involves the skin, infratemporal fossa, ascending ramus of the mandible, or mastoid process, more extensive surgical procedures (e.g., composite resection, lateral temporal bone resection, or radical parotidectomy) may become necessary.

Table 3 American Joint Committee on Cancer Staging System for Major Salivary Gland Tumors

Stage	T	N	M

IVB	T4b Any T	Any N N3	M0 M0
IVC	Any T	Any N	M1

Table 4 Principles of Treatment of Parotid Tumors

Adequate local excision of tumor, based on extent of primary lesion
Preservation of facial nerve if possible
Elective neck dissection reserved for selected patients
Postoperative radiotherapy when indicated (in appropriate fields)
Prognosis determined primarily by stage and grade of tumor

Patients with preoperative facial weakness or paralysis will often require sacrifice of the main trunk of the facial nerve. If the tumor involves only an isolated branch of the facial nerve, the surgeon can elect to selectively sacrifice the involved branch alone. Following nerve sacrifice, nerve grafting should be considered in the same procedure. Reconstruction of the facial nerve can be performed with a nerve graft from the greater auricular nerve, medial or lateral antecubial cutaneous nerve, sural nerve, and ansa hypoglossi, among others. The functional results of nerve grafting vary considerably, depending on the age of the patient, the extent of the disease, and the identification of and appropriate anastomosis to the peripheral branches of the facial nerve. If postoperative radiation therapy is envisioned, its potential deleterious effects on nerve regeneration should be considered.

FACIAL NERVE MONITORING

Postoperative facial weakness is a frequent complication of parotid surgery and is the most feared complication for both the patient and the surgeon. Transient facial dysfunction after parotidectomy ranges from 20 to 40%, whereas permanent paralysis has been reported to be as high as 5%. Continuous visual observation of the patient's ipsilateral face by the assistant surgeon or nurse has historically been the traditional method of facial nerve monitoring during a parotidectomy. More recently, however, facial nerve stimulators and continuous electromyographic neuromonitoring of the facial nerve have been employed by surgeons as a means to assist in nerve identification, to provide additional indication for what is "safe" to cut, and to reduce operative time.

Although a few small retrospective case-control comparisons have noted a significant reduction in the rates of temporary and/or permanent facial weakness with the use of these electrophysiologic devices,²⁹ the vast majority of studies have failed to demonstrate a significant improvement in postoperative facial nerve function outcome.^{30,31} Given the exceedingly low incidence of inadvertent permanent facial paralysis in parotid surgery, however, Eisele and colleagues pointed out that a prospective, randomized study would need, at minimum, 1,000 patients to demonstrate a reduction in permanent facial nerve injury from 2% to 1%.³² Accordingly, the authors suggested that a large, multi-institutional study will be needed to ascertain the benefits and drawbacks of electrophysiologic nerve monitoring technologies and that surgeons who believe that patients will benefit from the information provided should continue to use the devices.

INTRAOPERATIVE FROZEN-SECTION ANALYSIS

The role of intraoperative frozen-section examination in the evaluation of a parotid mass, like that of fine-needle aspiration biopsy, is the subject of considerable debate. Nevertheless, frozen-section examination has been found to be useful for distinguishing salivary processes from nonsalivary processes and benign disease from malignant disease. In 80 to 90% of cases, the findings from intraoperative frozen-section examination correlate with the final pathologic diagnosis.³³ If frozen-section examination shows a benign tumor and confirms the presumed preoperative diagnosis, lateral superficial parotidectomy should be sufficient. If frozen-section examination shows high-grade mucoepidermoid carcinoma in a

patient without evidence of cervical disease, selective neck dissection may be considered for staging purposes. Moreover, if frozen-section examination provides a definitive diagnosis of malignancy, further decisions about the extent of parotidectomy and possible selective neck dissection can be made accordingly. If the pathology is unrevealing, the procedure originally planned can be performed, and any further interventions, if required, can be dictated by the final pathologic diagnosis. Notably, significant caution should be exercised when deciding on facial nerve preservation or sacrifice based solely on frozen-section results as frozen-section classification of the wide variety of parotid tumors (both benign and malignant) is often difficult and will often depend on the experience of the frozen-section pathologist.

NECK DISSECTION

Overall, about 10 to 20% of patients with malignant parotid tumors present with clinically detectable cervical lymphadenopathy, most frequently in levels II and III. Nodal metastasis reduces the survival rate by roughly 50%.^{11,21,34} Patients with clinically or radiologically positive cervical metastases are treated with either a comprehensive, modified radical, or selective neck dissection, depending on the extent of the disease. However, the surgical management of patients with salivary malignancies who have no detectable cervical lymphadenopathy continues to be a matter of debate. Studies have revealed that only 12 to 16% of patients without clinical evidence of cervical disease demonstrated pathologically positive nodes.^{25,35} In view of the low incidence of occult metastases, these investigators do not recommend routine elective treatment of the neck.

Other authors have investigated the patient and tumor factors that may predict the presence of neck disease. Two large population studies identified older age, facial nerve paralysis, extraparotid involvement, higher tumor grade, and perilymphatic invasion as variables predictive of occult cervical disease.^{34,36} In addition, Bhattacharyya and Fried determined that tumor size and histopathologic type were also predictors of regional disease and identified adenocarcinoma and SCC as histopathologies with the highest odds ratios for nodal metastases.³⁴ Similarly, Regis De Brito Santos and colleagues found that the variables that showed the highest correlation with the incidence of lymph node metastasis were the histopathologic type (i.e., adenocarcinoma, undifferentiated carcinoma, high-grade mucoepidermoid carcinoma, SCC, or salivary duct carcinoma) and tumor stage.³⁷

Accordingly, an elective neck dissection may be considered in patients with advanced-stage primary tumors, those whose tumors are of high histologic grades, and those whose tumors are of certain specific histologic types. A selective neck dissection may be performed to remove levels IB, II, III, and the upper part of V for the purposes of staging.³⁸ However, a more comprehensive neck dissection that encompasses levels I through V may be necessary in patients who present with clinically or radiologically apparent cervical metastases.

RADIATION THERAPY

Candidates for postoperative radiation therapy include patients with advanced-stage disease, a large primary tumor, close or positive margins, nodal disease, perineural spread, soft tissue extension, preoperative facial nerve dysfunction, or

Table 5 Indications for Postoperative Radiation Therapy for Parotid Cancer

Aggressive, highly malignant tumor
Invasion of adjacent tissues outside parotid capsule
Regional lymph node metastases

Skin invasion
Facial nerve dysfunction
Perineural growth
Positive surgical margins
Soft tissue invasion
Treatment type

high-grade tumors [see Table 5].^{39,40} Accordingly, postoperative radiation therapy is suggested for all patients with parotid malignancy other than those with low-grade T1 or T2 tumors and clear surgical margins. Combined surgical and radiation therapy has been shown to result in 5- and 10-year survivals of as high as 95% and 84%, respectively.⁴¹

A role for radiation therapy for the treatment of an N0 neck in lieu of an elective neck dissection has been proposed, and there is some evidence to suggest that elective irradiation is as effective as elective neck dissection.²⁵ Some authors have proposed that postoperative patients who will already be requiring radiation therapy for additional primary-site sterilization are excellent candidates for elective radiation of the neck.⁴²

Additionally, there is substantial interest in the potential role of neutron radiotherapy as a primary treatment modality for certain parotid malignancies, including advanced inoperable cancers, adenoid cystic carcinomas, and recurrent pleomorphic adenomas, and for poor surgical candidates. Particle radiation may be of particular benefit in adenoid cystic carcinoma to treat perineural extension. Although additional work and further data on survival and related complications await this treatment modality, neutron radiotherapy may be the best option currently available for patients with inoperable parotid cancer.⁴³

Survival

Survival of patients with parotid gland malignancies is influenced by multiple factors [see Table 6]. The various histopathologies with variable aggressiveness will naturally exert different influences on mean survival durations and rates; histopathologic distributions and survival estimates of parotid gland cancers extracted from a national cancer database are provided in Table 7.⁴⁴ In this study, acinar cell carcinomas and mucoepidermoid carcinomas exhibited the best survival, whereas carcinoma ex pleomorphic adenoma, adenocarcinomas, and SCCs displayed substantially poorer survivals. Of note, separate survival analyses of the different grades of mucoepidermoid carcinoma demonstrated statistically significant differences in overall survival according to grade.

In addition to histopathology, increasing age, tumor size, tumor grade, extraglandular extension, and the presence of cervical disease all significantly and negatively impacted survival, whereas the use of external-beam radiation therapy provided a statistically significant survival benefit.^{44,45} Moreover, Lima and colleagues concluded in their institutional experience that the presence of facial nerve dysfunction also negatively influenced prognosis.²¹

3 NECK MASS

Christopher Scally, MD, and Gerard M. Doherty, MD*

Assessment of a Neck Mass

Clinical Evaluation

HISTORY

The evaluation of any neck mass begins with a careful history taken with the differential diagnosis in mind [see

Table 1] because directed questions can narrow down the diagnostic possibilities and focus subsequent investigations. For example, in younger patients, one might suspect congenital or inflammatory lesions, whereas in older adults, the first concern is often neoplasia.

The duration and growth rate of the mass are important: malignant lesions are more likely to grow rapidly than benign ones, which may grow and shrink. The location of the mass in the neck can also narrow the list of possibilities. This is particularly important for differentiating congenital masses from neoplastic or inflammatory ones because each type usually occurs in particular locations. In addition, the location of a neoplasm has both diagnostic and prognostic significance. The possibility that the mass is an infectious or inflammatory process should also be assessed. One should evaluate for evidence of infection or inflammation (e.g., fever, pain, or tenderness); a recent history of tuberculosis, sarcoidosis, or fungal infection; the presence of dental problems; and a history of trauma to the head and neck. Masses that appear inflamed or infected are far more likely to be benign.

Finally, factors suggestive of cancer include a history of malignancy elsewhere in the head and neck (e.g., a history of skin cancer, melanoma, thyroid cancer, or head and neck cancer); night sweats (suggestive of lymphoma); excessive exposure to the sun (a risk factor for skin cancer); smoking or excessive alcohol consumption (risk factors for squamous cell carcinoma of the head and neck); nasal obstruction or bleeding, otalgia, odynophagia, dysphagia, or hoarseness (suggestive of a malignancy in the upper aerodigestive tract); or exposure to low-dose therapeutic radiation (a risk factor for thyroid cancer).

Financial disclosure information is located at the end of this chapter before the references.

PHYSICAL EXAMINATION

The head and neck examination is challenging because much of the area to be examined is not easily seen. Patience and practice are necessary to master the

special instruments and techniques of examination. A head and neck examination is usually performed with the patient sitting in front of the physician. Constant repositioning of the head is necessary to obtain adequate visualization of the various areas. Gloves must be worn during the examination, particularly if the mucous membranes are to be examined. Good illumination is essential. Fiberoptic endoscopy with a flexible laryngoscope and a nasopharyngoscope is a common component of the physical examination for evaluating

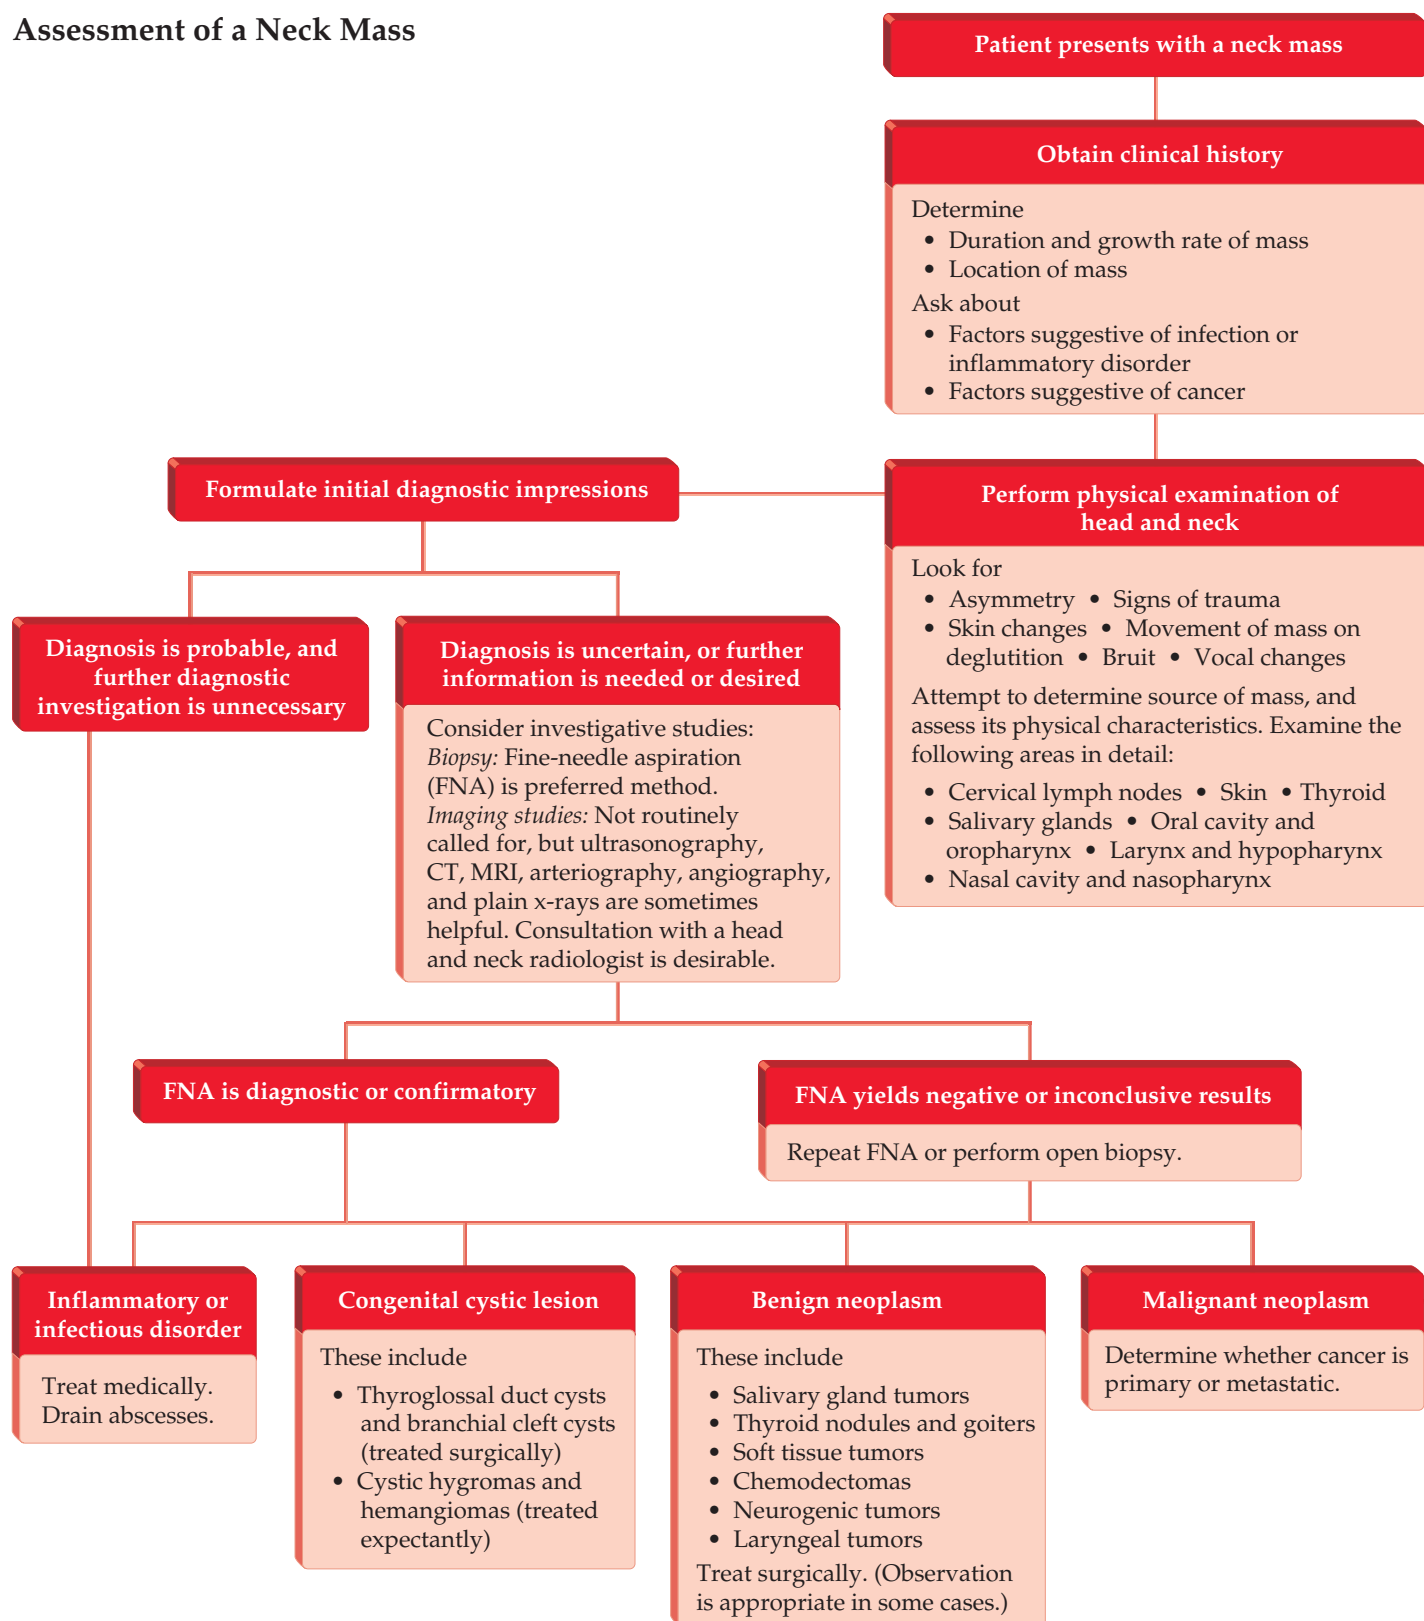

Table 1 Etiology of Neck Mass

Inflammatory and infectious disorders
Acute lymphadenitis (bacterial or viral infection)
Subcutaneous abscess (carbuncle)
Infectious mononucleosis
Cat-scratch fever
AIDS
Tuberculous lymphadenitis (scrofula)
Fungal lymphadenitis (actinomycosis)
Sarcoidosis
Congenital cystic lesions
Thyroglossal duct cyst
Branchial cleft cyst
Cystic hygroma (lymphangioma)
Vascular malformation (hemangioma)
Laryngocele
Benign neoplasms
Salivary gland tumor
Thyroid nodules or goiter
Soft tissue tumor (lipoma, sebaceous cyst)
Chemodectoma (carotid body tumor)
Neurogenic tumor (neurofibroma, neurilemmoma)
Laryngeal tumor (chondroma)
Malignant neoplasms
Primary
Salivary gland tumor
Thyroid cancer
Upper aerodigestive tract cancer
Soft tissue sarcoma
Skin cancer (melanoma, squamous cell carcinoma, basal cell carcinoma)
Lymphoma
Metastatic
Upper aerodigestive tract cancer
Skin cancer (melanoma, squamous cell carcinoma)
Salivary gland tumor
Thyroid cancer
Adenocarcinoma (breast, gastrointestinal tract, genitourinary tract, lung)
Unknown primary tumor

Assessment of a Neck Mass

the larynx, the nasopharynx, and the paranasal sinuses, especially when these areas cannot be adequately inspected with other techniques.

The examination should begin with inspection for asymmetry, signs of trauma, and skin changes. The examiner should ask the patient to swallow to observe whether the mass moves with deglutition and should palpate the neck from both the front and behind. Auscultation can detect audible bruits. One should also both listen to and ask about the patient's voice, changes in which may suggest either a laryngeal tumor or recurrent nerve dysfunction from locally invasive thyroid cancer.

During the physical examination, one should be thinking about the following questions: What structure is the neck mass arising from? Is it a lymph node? Is the mass arising from a normally occurring structure, such as the thyroid gland, a salivary gland, a nerve, a blood vessel, or a muscle? Or is it arising from an abnormal structure, such as a laryngocele, a branchial cleft cyst, or a cystic hygroma? Is the mass soft, fluctuant, easily mobile, well encapsulated, and smooth? Or is it firm, poorly mobile, and fixed to surrounding structures? Does it pulsate? Is there a bruit? Does it appear to be superficial, or is it deeper in the neck? Is it attached to the skin? Is it tender?

The following areas of the head and neck are examined in some detail.

Cervical Lymph Nodes

The cervical lymphatic system consists of interconnected groups or chains of nodes that parallel the major neurovascular structures in the head and neck. The skin and mucosal surfaces of the head and neck all have specific and predictable nodes associated with them. The classification of cervical lymph nodes has been standardized to comprise six levels [see Figure 1]. Accurate determination of lymph node level on physical examination and in surgical specimens not only helps establish a common language among clinicians but also permits comparison of data among different institutions.

The location, size, and consistency of lymph nodes furnish valuable clues to the nature of the primary disease. Other physical characteristics of the adenopathy should be noted as well, including the number of lymph nodes affected, their mobility, their degree of fixation, and their relation to surrounding anatomic structures. One can often establish a tentative diagnosis on the basis of these findings alone. For example, soft or tender nodes are more likely to derive from an inflammatory or infectious condition, whereas hard, fixed, painless nodes are more likely to represent metastatic cancer. Multiple regions of enlarged lymph nodes are usually a sign of systemic disease (e.g., lymphoma, tuberculosis, or infectious mononucleosis), whereas solitary nodes are more often due to malignancy. Firm, rubbery nodes are typical of lymphoma.

The submental and submandibular nodes (level I) are palpated bimanually. The three levels of internal jugular chain nodes (levels II, III, and IV) are best examined by gently rolling the sternocleidomastoid muscle between the thumb and the index finger. The posterior triangle nodes (level V) are palpated posterior to the sternocleidomastoid.

The tracheoesophageal groove nodes (level VI) are then palpated.

Skin

Careful examination of the scalp, the ears, the face, the oral cavity, and the neck can identify potentially malignant skin lesions, which may give rise to lymph node metastases.

Thyroid Gland

The thyroid gland is first observed as the patient swallows; it is then palpated and its size and consistency are assessed to determine whether it is smooth, diffusely enlarged, or nodular and whether one nodule or several are present. If it is unclear whether the mass arises from the thyroid, one can clarify the point by asking the patient to swallow and watching to see whether the mass moves upward with the larynx. Signs of superior mediastinal syndrome (e.g., cervical venous engorgement and facial edema) suggest retrosternal extension of a thyroid goiter. Elevation of the arms above the head can elicit this finding in a patient with a substernal goiter (a positive Pemberton sign). The larynx and trachea are examined, with special attention to the cricothyroid membrane, over which Delphian nodes can be palpated. These nodes can be an indication of thyroid or laryngeal cancer.

Major Salivary Glands

Examination of the paired parotid and submandibular glands involves not only palpation of the neck but also an intraoral examination to inspect the duct openings. The submandibular glands are best assessed by bimanual palpation, with one finger in the mouth and one in the neck. They are normally lower and more prominent in older patients. The parotid glands are often palpable in the neck, although the deep lobe cannot always be assessed. A mass in the region of the tail of the parotid must be distinguished from enlarged level II jugular nodes. The oropharynx is inspected for distortion of the lateral walls. The parotid (Stensen) duct may be found opening into the buccal mucosa, opposite the second upper molar.

Oral Cavity and Oropharynx

The lips should be inspected and palpated. Dentures should be removed before the mouth is examined. The buccal mucosa, the teeth, and the gingiva are then inspected. The patient should be asked to elevate the tongue so that the floor of the mouth can be examined and bimanual inspection performed. The tongue should be inspected both in its normal position in the mouth and during protrusion.

Most of the oropharyngeal contents are easily visualized if the tongue is depressed. Only the anterior two thirds of the tongue are clearly visible on examination, however. The base of the tongue is best inspected using a mirror. In most persons, the tongue base can be palpated, although with some discomfort to the patient. The ventral surface of the tongue must also be carefully inspected and palpated.

The hard palate is examined by gently tilting the patient's head backward, and the soft palate is inspected by gently depressing the tongue with a tongue blade. The movement of the palate is assessed by having the patient say "ahh."

Figure 1 Cervical lymph nodes. Inset: Classification of cervical lymph nodes by anatomic level.

The tonsils are then examined. They are usually symmetrical but may vary substantially in size. For example, in young patients, hyperplastic tonsils may almost fill the oropharynx, but in adult patients, this is an uncommon finding. Finally, the posterior pharyngeal wall is inspected.

Larynx and Hypopharynx

The larynx and the hypopharynx are best examined by indirect or direct laryngoscopy. A mirror is warmed, and the patient's tongue is gently held forward to increase the space

between the oropharyngeal structures. The mirror is carefully introduced into the oropharynx without touching the base of the tongue. The oropharynx, the larynx, and the hypopharynx can be inspected by changing the angle of the mirror.

The lingual and laryngeal surfaces of the epiglottis are examined. Often the patient must be asked to phonate to bring the endolarynx into view. The aryepiglottic folds and the false and true vocal cords should be identified. The mobility of the true vocal cords is then assessed: their resting

position is carefully noted, and their movement during inspiration is recorded. Normally, the vocal cords abduct during breathing and move to the median position during phonation. The larynx is elevated when the patient attempts to say “eeeeee”; this allows one to observe vocal cord movement and to better visualize the piriform sinuses, the post-cricoid hypopharynx, the laryngeal surface of the epiglottis, and the anterior commissure of the glottic larynx. Passage of a fiberoptic laryngoscope through the nose yields a clear view of the hypopharynx and the larynx. This procedure is well tolerated by almost all patients, particularly if a topical anesthetic is gently sprayed into the nose and swallowed, thereby anesthetizing both the nose and the pharynx.

Nasal Cavity and Nasopharynx

The nasopharynx is examined by depressing the tongue and inserting a small mirror behind the soft palate. The patient is instructed to open the mouth widely and breathe through it to elevate the soft palate. With the patient relaxed, a warmed nasopharyngeal mirror is carefully placed in the oropharynx behind the soft palate without touching the mucosa.

The nasal septum, the choanae, the turbinates, and the eustachian tube orifices are systematically assessed. The dorsum of the soft palate, the posterior nasopharyngeal wall, and the vault of the nasopharynx should also be inspected. The exterior of the nose should be carefully examined, and the septum should be inspected with a nasal speculum. Polyps or other neoplasms can be mistaken for turbinates.

Careful evaluation of the cranial nerves is essential, as is examination of the eyes (including assessment of ocular movement and visual activity), the external ear, and the tympanic membrane.

Additional Areas

The remainder of the physical examination is also important, particularly as regards the identification of a possible source of metastases to the neck. Other sets of lymph nodes—especially axillary and inguinal nodes—are examined for enlargement or tenderness. Women should undergo complete pelvic and rectal examination. Men should undergo rectal, testicular, and prostate examinations; tumors from these organs may metastasize to the neck, albeit rarely.

Developing a Differential Diagnosis

Once a comprehensive history and examination have been performed, one is likely to have a better idea of the etiology of the mass.

In some patients, the findings are clear enough to strongly suggest a specific disease entity. For example, a rapidly developing mass that is soft and tender to palpation is most likely a reactive lymph node from an acute bacterial or viral illness. A slow-growing facial mass associated with facial nerve deficits is probably a malignant parotid tumor.

A thyroid nodule with an adjacent abnormal lymph node in a young patient probably represents thyroid cancer. In an elderly patient with a substantial history of smoking and alcohol use, a neck mass may be a metastasis from squamous cell carcinoma in the aerodigestive tract.

The initial diagnostic impressions and the degree of certainty attached to them determine the next steps in the workup and management of a neck mass; options include empirical therapy, ultrasonographic scanning, computed tomography (CT), fine-needle aspiration (FNA), and observation alone. For example, in a patient with suspected bacterial lymphadenitis from an oral source, empirical antibiotic therapy with close follow-up is a reasonable approach. In a patient with a suspected parotid tumor, the best first test is a CT scan: the tumor probably must be removed, which means that one will have to ascertain the relation of the mass to adjacent structures. In a patient with suspected metastatic cancer, FNA is a sensible choice: it will confirm the presence of malignancy and may suggest a source of the primary cancer.

Investigative Studies

Neck masses of suspected infectious or inflammatory origin can be observed for short periods. Most neck masses in

adults, however, are abnormal and are often manifestations of serious underlying conditions. In most cases, therefore, further diagnostic evaluation should be rigorously pursued.

ULTRASONOGRAPHY

Ultrasonography of the neck can be extremely useful in clarifying physical examination findings and supplying additional definitive information. In many clinics, ultrasonography is considered an extension of the physical examination and is applied for nearly all patients with neck masses. Ultrasonography can also be useful to guide tissue sampling and is helpful for mapping of normal or abnormal lymph nodes, for characterizing lesions as cystic or solid, and for defining the risk of some individual lesions (especially thyroid lesions) of being malignant. Ideally, point-of-care ultrasound examination by the treating physician can guide and clarify the subsequent evaluation.

TISSUE SAMPLING

Whether or not the history and the physical examination strongly suggest a specific diagnosis, the information obtained by sampling tissue from the neck mass is often highly useful. In many cases, biopsy establishes the diagnosis or, at least, reduces the diagnostic possibilities. At present, the preferred method of obtaining biopsy material from a neck mass is FNA, which is generally well tolerated and can usually be performed without local anesthesia. Although FNA is, on the whole, both safe and accurate, it is an invasive diagnostic procedure and carries a small but definable risk of potential problems (e.g., bleeding and sampling error). Accordingly, FNA should be done only when the results are likely to influence management.

FNA can be used to sample cystic or solid lesions and can often diagnose malignancy. It has become the standard for making treatment decisions in patients with thyroid nodules and for assessing for suspicious adenopathy for treatment planning. Benign FNA results should not be considered the end point of any search and do not rule out cancer.

Several studies have shown FNA to be approximately 90% accurate in establishing a definitive diagnosis.¹ Lateral cystic neck masses that collapse on aspiration usually represent hygromas, branchial cleft cysts, or cystic degeneration of a metastatic papillary thyroid cancer, although the cystic nature of these lesions is best determined on ultrasonography. Fluid from these masses is sent for cytologic examination. If both cystic and solid components are evident on a sonogram, or if a palpable mass remains after cyst aspiration, then tissue sampling should target the solid component as the morphology of the cells will be better preserved.

If a complete physical examination including ultrasonography has been completed and the FNA is not diagnostic, then an open biopsy may be necessary to obtain a specimen for histologic sections and microbiologic studies. It is estimated that open biopsy eventually proves necessary in about 10% of patients with a malignant mass. For an open biopsy, it is important to orient skin incisions within the boundaries of a neck dissection; the incisions can then, if necessary, be extended for definitive therapy or reexcised if reoperation subsequently proves necessary.

IMAGING

Diagnostic imaging beyond ultrasound studies should be used selectively in the evaluation of a neck mass; imaging studies should be performed only if the results are likely to affect subsequent therapy. Such studies often supply useful information about the location and characteristics of the mass and its relation to adjacent structures. Diagnostic imaging is particularly useful when a biopsy has been performed and a malignant tumor identified. In such cases, these studies can help establish the extent of local disease and the presence or absence of metastases.

CT is useful for differentiating cysts from solid neck lesions and for determining whether a mass is within or outside a gland or nodal chain.² In addition, CT can delineate small tongue base or tonsillar tumors that have a minimal mucosal component. Magnetic resonance imaging (MRI) provides much the same information as CT. T₂-weighted gadolinium-enhanced scans are particularly useful for delineating the invasion of soft tissue by tumor: endocrine tumors are often enhanced on such scans. Fluorodeoxyglucose (FDG) positron emission tomography (PET) is increasingly employed in the diagnosis and staging of both primary and metastatic head and neck malignancies, including squamous cell carcinoma, thyroid cancer, lymphoma, and melanoma.³ FDG-PET is generally reserved for specific situations, however, rather than as a primary imaging modality. FDG-PET-positive, radioiodine-negative, metastatic thyroid cancers are more aggressive than their radioiodine-avid counterparts, for example.

Arteriography is useful mainly for evaluating vascular lesions and tumors fixed to the carotid artery. Angiography is helpful for evaluating the vascularity of a mass, its specific blood supply, or the status of the carotid artery but

provides very little information about the physical characteristics of the mass. Plain radiographs of the neck are rarely helpful in differentiating neck masses, but a chest x-ray can often confirm a diagnosis (e.g., in patients with lymphoma, sarcoidosis, or metastatic lung cancer).

It is important to communicate with the radiologist: an experienced head and neck radiologist may be able to offer the surgeon valuable guidance in choosing the best diagnostic test in a specific clinical scenario. Furthermore, providing the radiologist with a detailed clinical history facilitates interpretation of the images.

Management of Specific Disorders

CERVICAL ADENOPATHY

Anatomy

The lymph nodes of the neck are typically

divided into six levels [see Table 2 and Figure 1], based on common patterns of metastatic spread.⁴ These six levels correspond to the submandibular and submental nodes (level I), the jugular nodes (levels II to IV), the posterior triangle nodes (level V), and the anterior triangle nodes (level VI). The boundaries of level I are the mandible superiorly, the anterior belly of the digastric muscle anteriorly, and the stylohyoid muscle posteriorly. Malignant nodes in this level most commonly contain metastases from cancers of the lips, the oral cavity, or the facial skin.

Level II contains nodes located near the upper third of the internal jugular vein. The anterior boundary of level II is the stylohyoid muscle; the posterior boundary is the posterior border of the sternocleidomastoid. Level II extends inferiorly to the level of the hyoid bone. Level III relates to the middle third of the jugular vein. The superior border is the hyoid bone, the inferior border is the level of the cricoid cartilage, and the anterior and posterior borders are the sternohyoid and sternocleidomastoid muscles, respectively. Level II and level III lymph nodes are common sites for lymph node metastases from primary cancers of the oropharynx, the larynx, and the hypopharynx.

Level IV contains nodes relating to the lower third of the internal jugular vein. Its anterior and posterior borders are the same as those for level III; the superior border is the cricoid cartilage, and the inferior border is the superior edge of the clavicle. Metastases in level IV lymph nodes can arise from cancers of the upper aerodigestive tract, cancers of the thyroid gland, or cancers arising below the clavicle.

Level V consists of the posterior triangle of the neck and contains several nodal groups: the spinal accessory, transverse cervical, and supraclavicular nodes. Nodal metastases in the posterior triangle can arise from nasopharyngeal and thyroid cancers and from squamous cell carcinoma or melanoma of the posterior scalp and the pinna of the ear. The eponymous Virchow node in the left supraclavicular region is a common site of distant metastasis. The anterior border of level V is the sternocleidomastoid; the posterior border is the anterior edge of the trapezius muscle. Level V extends

Table 2 Classification of Cervical Lymph Nodes

Level	Nodes	Common Sources of Metastatic Disease
I	Submental nodes Submandibular nodes	Oral cavity and lip, facial skin
II	Upper internal jugular chain nodes	Oropharynx, larynx, hypopharynx
III	Middle internal jugular chain nodes	Oropharynx, larynx, hypopharynx
IV	Lower internal jugular chain nodes	Upper aerodigestive tract, thyroid
V	Spinal accessory nodes Transverse cervical nodes	Remote metastases (Virchow node); posterior scalp
VI	Tracheoesophageal groove nodes	Thyroid, larynx

superiorly from the point at which the sternocleidomastoid and trapezius converge to the clavicle inferiorly.

Level VI contains the lymph nodes of the anterior compartment of the neck. The borders are the hyoid superiorly and the sternal notch inferiorly, and this level extends laterally to the carotid arteries on each side. Nodes in level VI commonly contain metastases from thyroid cancer, as well as from laryngeal cancers.

Investigative and Diagnostic Studies

Lymph node enlargement is a frequent finding with a wide differential diagnosis. Most commonly, lymph node enlargement occurs as a reaction to acute infection; however, given the potential for alternate causes such as malignancy, a benign diagnosis cannot be assumed. A careful history and thorough examination, as well as consideration by the clinician of all potential causes, are essential. Acute infection of the neck (cervical adenitis) is most often the result of dental infection, tonsillitis, pharyngitis, viral upper respiratory tract infection, or skin infection. In this situation, the enlarged lymph nodes are usually just posterior and inferior to the angle of the mandible. Signs of acute infection (e.g., fever, malaise, and a sore mouth or throat) are usually present. A constitutional reaction, tenderness of the cervical mass, and the presence of an obvious infectious source confirm the diagnosis. Treatment should be directed toward the primary disease and should include a monospot test for infectious mononucleosis.

For patients with cervical adenopathy without an obvious acute infection, further investigation is indicated. Various chronic infections (e.g., tuberculosis, fungal lymphadenitis, syphilis, cat-scratch fever, and AIDS) may also involve cervical lymph nodes. Certain chronic inflammatory disorders (e.g., sarcoidosis) may present with cervical lymphadenopathy as well. Because of the chronic lymph node involvement, these conditions are easily confused with neoplasms, especially lymphomas. Biopsy is occasionally necessary; however, skin tests and serologic studies are often more useful for establishing a diagnosis. Treatment of these conditions is primarily medical; surgery is reserved for complications.

In adult patients with cervical adenopathy and no clear infectious etiology, there is a high risk of malignancy, and FNA is recommended. FNA may provide a conclusive diagnosis or further reduce the range of diagnostic possibilities. FNA is also useful in patients with a known distant malignancy in whom confirmation of metastases is needed for

staging and for planning therapy, as well as in patients with a primary tumor of the head and neck who are not candidates for operation but in whom a tissue diagnosis is necessary for appropriate nonsurgical therapy to be initiated. A wide variety of primary tumors may metastasize to the cervical lymph nodes, and therapy depends on the primary site and the type and stage of the tumor.

FNA of an enlarged cervical node does have limitations. Sampling error or an inadequate sample may occur; in these cases, a repeat aspiration or an excisional biopsy may be useful.

When lymphoma and metastatic squamous cell carcinoma are diagnostic possibilities, FNA alone is often incapable of determining the precise histologic subtype for lymphoma, but it is usually capable of distinguishing a lymphoproliferative disease from metastatic squamous cell carcinoma. This is a crucial distinction in that the two neoplasms are treated in drastically different ways.

If a lymphoma is suspected, FNA is typically followed by open biopsy, frozen-section confirmation, and submission of fresh tissue for further pathologic characterization. The intact node is placed in normal saline and sent directly to the pathologist for analysis of cellular content and nodal architecture and identification of lymphocyte markers. If, however, metastatic squamous cell carcinoma is suspected, FNA usually suffices for establishing the diagnosis and formulating a treatment plan, which is specific to the site and size of the primary tumor but often includes chemotherapy and radiation initially. In this setting, performing an open biopsy can lead to significant wound healing complications; there is no need to incur this risk when FNA is sufficient to initiate treatment.

THYROID NODULES: BENIGN AND MALIGNANT THYROID DISEASE

Thyroid disease is a relatively common cause of neck mass. Nearly 4% of the population have a palpable thyroid nodule. The majority of thyroid nodules are benign; however, approximately 5% of these lesions are malignant.⁵ The evaluation of a thyroid nodule begins with a careful history, focusing on both local symptoms (dysphagia, hoarseness, vocal changes, sleep apnea) and systemic symptoms, as well as a family history of thyroid disease and past exposure to radiation [see Figure 2]. A past history of radiation exposure in particular is associated with increased risk of malignancy. After a thorough history and examination, including

Figure 2 Management algorithm for thyroid nodules. FNA = fine-needle aspiration; PTC = papillary thyroid cancer; TSH = thyroid-stimulating hormone.

ultrasonography, further investigation is usually warranted. This can include laboratory studies, further imaging, and cytologic assessment.⁶

A serum thyroid-stimulating hormone (TSH) level should be obtained on any patient with a palpable thyroid nodule or a nodule detected incidentally on imaging. If the serum TSH is low, then radionuclide scanning should be

performed. If the nodule is hyperfunctioning, then no further evaluation is needed as the risk of malignancy is low. Patients with a hyperfunctioning nodule, a depressed serum TSH, and clinical symptoms may then be evaluated and medically treated for hyperthyroidism. Additionally, an elevated TSH is associated with a small increased risk of malignancy.

Ultrasonography should be performed for any patient with a palpable thyroid nodule as part of the initial evaluation. Sonography can indicate the size of the nodule and its position within the gland; it can identify features that suggest a benign or malignant nodule. A thorough ultrasound examination may also help the practitioner identify suspicious cervical adenopathy, additional nodules not palpated on examination, or other abnormalities. Findings of microcalcifications, irregular margins, and increased vascularity are suggestive of papillary thyroid cancer. Follicular cancers are often iso- or hyperechoic with a peripheral “halo” of decreased echogenicity.

FNA is recommended for the majority of thyroid nodules detected either by palpation or imaging. Table 3 outlines the current recommendations for FNA based on clinical history, size of the nodule, and imaging characteristics. FNA is not routinely recommended for nodules smaller than 1 cm; however, in patients with a higher risk of malignancy, including those with a family history of thyroid cancer or a history of radiation exposure in childhood or adolescence, FNA of a smaller nodule may be indicated. FNA can be performed either by palpation or ultrasound guidance. The latter is recommended for most nodules as it decreases the occurrence of nondiagnostic results but especially for those that are predominantly cystic, located posteriorly in the thyroid lobe, or nonpalpable. FNA is useful in the evaluation of thyroid nodules in children.⁷

Interpretation of FNA Cytology

FNA results can be classified as nondiagnostic, benign, malignant, suspicious for malignancy, or indeterminate.⁸ Nearly 20% of FNAs are nondiagnostic; repeated FNA under ultrasound guidance can lead to a diagnostic cytology specimen in 50 to 75% of these nodules. For nodules that

repeatedly yield nondiagnostic samples, surgical excision should be considered, particularly if the nodule is solid rather than cystic. For nodules with FNA findings diagnostic of malignancy, surgical resection is recommended. For benign nodules, no further investigation is required. However, if a benign nodule continues to grow, as demonstrated on follow-up ultrasonography, repeated biopsy should be performed, and a diagnostic thyroid lobectomy may be indicated.

Nodules with indeterminate cytology are typically reported as “cellular atypia,” “Hürthle cell neoplasm,” or “follicular neoplasm” and are an area of significant debate in terms of management. Many molecular markers and imaging studies have been evaluated for a possible role in improving the diagnostic accuracy in patients with these lesions. Most recently, the role of ¹⁸FDG-PET has been explored as a promising method of determining malignant potential; however, the findings of most studies of FDG-PET utility show low specificity. Currently, for indeterminate lesions interpreted as “suspicious for papillary carcinoma” or “Hürthle cell neoplasm,” surgical resection is recommended.⁶ For the remainder of indeterminate lesions, a radionuclide study can be considered; if the nodule is not hyperfunctioning, then surgical resection may be warranted.

Thyroid Cancer: Overview of Surgical and Medical Management

The procedure of choice for a papillary thyroid cancer that is small (< 1 cm in diameter) and confined to the gland, as well as for minimally invasive follicular thyroid cancer, is a thyroid lobectomy. For the remainder of papillary or follicular cancers, as well as Hürthle cell and medullary thyroid cancer, total or near-total thyroidectomy is preferable. Patients with thyroid nodules and a history of radiation exposure should also undergo a total thyroidectomy as approximately 40% of these patients have at least one additional focus of papillary thyroid cancer. Total thyroidectomy also allows the use of ¹³¹I scanning to monitor for recurrence and increases the sensitivity of thyroglobulin and calcitonin assays in posttreatment surveillance. New information regarding the molecular basis for thyroid neoplasia is gradually informing the individualized care for patients with these tumors.⁹

Patients with medullary thyroid cancer should additionally undergo bilateral central neck dissection, screening for *ret* proto-oncogene mutations, and screening for pheochromocytoma.¹⁰ Anaplastic thyroid cancer is best treated with a combination of chemotherapy and radiation therapy, in conjunction with removal of as much of the neoplasm as can be safely excised. Most patients with thyroid lymphomas should receive chemotherapy, radiation therapy, or a combination of the two.

Table 3 Thyroid Nodule Assessment	
Nodule Sonographic or Clinical Features	Recommended Size Threshold for FNA
High-risk history	
Nodule with suspicious sonographic features	> 5 mm
Nodule without suspicious sonographic features	> 5 mm
Abnormal cervical lymph nodes	All
Microcalcifications present in nodule	≥ 1 cm
Solid nodule	
And hypoechoic	> 1 cm

NEOPLASTIC MASSES

Salivary Gland Tumor

Salivary gland neoplasms usually present as an enlarging solid mass in front of

and below the ear, at the angle of the mandible, or in the submandibular triangle. Benign salivary gland lesions are often asymptomatic; malignant ones are often associated with seventh cranial nerve symptoms or skin fixation. Diagnostic imaging studies (CT or MRI) indicate whether the mass is salivary in origin but do not help classify it histologically. The diagnostic test of preference is open biopsy in the form of complete submandibular gland removal or superficial parotidectomy.

With any mass in or around the ear, one should be prepared to remove the superficial lobes of the parotid, the deep lobes, or both and to perform a careful facial nerve dissection. Any less complete approach reduces the chances of a cure: there is a high risk of implantation and seeding of malignant tumors. Benign mixed tumors make up two thirds of all salivary tumors; these must also be completely removed because recurrence is common after incomplete resection. Malignant lesions may require additional therapy with radiation or chemotherapy.¹¹

Soft Tissue Tumor (Lipoma, Sebaceous Cyst)

Superficial intracutaneous or subcutaneous masses may be sebaceous (or epidermal inclusion) cysts or lipomas. Final diagnosis and treatment usually involve simple surgical excision, often done as an office procedure with local anesthesia.

Chemodectoma (Carotid Body Tumor)

Carotid body tumors belong to a group of tumors known as chemodectomas (or, alternatively, as glomus tumors or nonchromaffin paragangliomas), which derive from the chemoreceptive tissue of the head and neck. Chemodectomas most often arise from the tympanic bodies in the middle ear, the glomus jugulare at the skull base, the vagal body near the skull base along the inferior ganglion of the vagus, and the carotid body at the carotid bifurcation. They are sometimes familial and can occur bilaterally.¹²

A carotid body tumor presents as a firm, round, slowly growing mass at the carotid bifurcation. Occasionally, a bruit is present. The tumor cannot be separated from the carotid artery by palpation and can usually be moved laterally and medially but not in a cephalocaudal plane. The differential diagnosis includes a carotid aneurysm, a branchial cleft cyst, a neurogenic tumor, and nodal metastases fixed to the carotid sheath. The diagnosis is made by CT or arteriography, which demonstrate a characteristic highly vascular mass at the carotid bifurcation. Neurofibromas tend to displace, encircle, or compress a portion of the carotid artery system, events that are readily demonstrated by carotid angiography.

Biopsy should be avoided. Chemodectomas are sometimes malignant and should therefore be removed in most cases to prevent subsequent growth and pressure symptoms. Fortunately, even malignant chemodectomas are usually low grade; long-term results after removal are generally excellent. Vascular surgical experience is desirable in that the tumors are very vascular and intimately involve the carotid artery, and clamping of the carotid artery may result in a stroke. Expectant treatment may be indicated in older or debilitated individuals. Radiotherapy may be helpful for patients with unresectable tumors.

Neurogenic Tumor (Neurofibroma, Neurilemmoma)

The most common neurogenic tumors in the head and neck, neurilemmomas (schwannomas) and neurofibromas, arise from the neurilemma and usually present as painless, slowly growing masses in the lateral neck. Neurilemmomas can be differentiated from neurofibromas only by means of histologic examination.

Given the potential these tumors possess for malignant degeneration and slow but progressive growth, surgical resection is indicated. This may include resection of the involved nerves, particularly with neurofibromas, which tend to be more invasive and less encapsulated than neurilemmomas.

Laryngeal Tumor

In rare cases, a chondroma may arise from the thyroid cartilage or the cricoid cartilage. It is firmly fixed to the cartilage and may present as a mass in the neck or as the cause of a progressively compromised airway. Surgical excision is indicated.

Lymphoma

Cervical adenopathy is one of the most common presenting symptoms in patients with Hodgkin and non-Hodgkin lymphoma. The nodes tend to be softer,

smoother, more elastic, and more mobile than nodes containing metastatic carcinoma. Rapid growth is common, particularly in non-Hodgkin lymphoma. Involvement of extranodal sites, particularly Waldeyer tonsillar ring, often occurs in patients with non-Hodgkin lymphoma; enlargement of these sites may provide a clue to the diagnosis. The diagnosis is usually suggested by FNA and then confirmed via excisional biopsy of an intact lymph node. Lymphoma is typically treated by radiation therapy, chemotherapy, or both depending on the disease's pathologic type and clinical stage.

Upper Aerodigestive Tract Cancer

Many localized tumors of the aerodigestive tract can be cured with surgery alone. Treatment of locally advanced squamous cell cancers, however, often necessitates a multimodality approach.¹³ Such an approach has traditionally consisted of surgery followed by radiation therapy, but recent data indicate that concurrent chemoradiotherapy has an additional beneficial effect as an adjuvant measure.^{14,15}

Chemoradiotherapy is also employed for unresectable disease, and induction chemotherapy may be administered preoperatively to reduce operative morbidity. Among the chemotherapeutic agents active against head and neck squamous cell cancers are the taxanes, cisplatin and fluorouracil, and various newer targeted agents (e.g., epidermal growth factor receptor antagonists).

Treatment planning for such patients depends on the tumor's location and stage, the patient's age, and the presence and severity of associated medical conditions, among

other factors.¹⁶ Consultation with a specialist in this field is generally required. Therefore, cancers involving the nose, the paranasal sinuses, the nasopharynx, the floor of the mouth, the tongue, the palate, the tonsils, the piriform sinus, the hypopharynx, or the larynx are best managed by an experienced head and neck oncologic surgeon in conjunction with a radiation therapist and a medical oncologist.

Soft Tissue Sarcoma

Malignant sarcomas are not common in the head and neck. The sarcomas most frequently encountered include rhabdomyosarcoma in children, fibrosarcoma, liposarcoma, osteogenic sarcoma (which usually arises in young adults), and chondrosarcoma. The most common head and neck sarcoma, however, is malignant fibrous histiocytoma (MFH). MFH occurs most frequently in the elderly and extremely rarely in children, but it can arise at any age. It is often difficult to differentiate from other entities (e.g., fibrosarcoma). MFH can occur in the soft tissues of the neck or involve the bone of the maxilla or the mandible. The preferred treatment is wide surgical resection; adjuvant radiation therapy and chemotherapy are being studied in clinical trials.

Rhabdomyosarcoma, usually of the embryonic form, is the most common form of sarcoma in children. It generally occurs near the orbit, the nasopharynx, or the paranasal sinuses. The diagnosis is confirmed by biopsy. A thorough search for distal metastases is important before treatment—consisting of a combination of surgical resection, radiation therapy, and chemotherapy—is begun.

Skin Cancer

Basal cell carcinomas are the most common of the skin malignancies. These lesions arise most commonly in areas that have been extensively exposed to sunlight (e.g., the nose, the forehead, the cheeks, and the ears). Treatment consists of local resection with adequate clear margins. Metastases are rare, and the prognosis is excellent. Inadequately excised and neglected basal cell carcinomas may ultimately spread to regional lymph nodes and can cause extensive local destruction of soft tissue and bone. For example, basal cell carcinoma of the medial canthus may invade the orbit, the ethmoid sinus, and even the brain. Periauricular basal cell carcinoma can spread across the cartilage of the ear canal or into the parotid gland. In such cases of locally advanced basal cell cancer or nodal involvement with tumor, patients may require more extensive surgical treatment (i.e., modified neck dissection). Postoperative radiation therapy is often administered to optimize local control and reduce the risk of recurrence.

Squamous cell carcinoma also arises in areas associated with extensive sunlight exposure; the lower lip and the pinna are the most common sites. Unlike basal cell carcinoma, however, squamous cell carcinoma tends to metastasize to both regional and distant sites. This tumor must also be excised with an adequate margin.

Melanoma is primarily classified on the basis of depth of invasion (as quantified by Clark level or Breslow thickness), location, and histologic subtype, although the prognosis is closely related to the thickness of the tumor [see Metastatic Disease, Metastatic Melanoma, *below*]. In addition to the

typical pigmented, irregularly shaped skin lesions, malignant melanoma can also arise on the mucous membranes of the nose or the throat, on the hard palate, or on the buccal mucosa. The treatment of choice is wide surgical resection. Radiation therapy, chemotherapy, and immunotherapy may be useful in specific situations.

METASTATIC DISEASE

Metastatic Squamous Cell Carcinoma

The basic principle in the management of metastatic squamous cell carcinoma

is wide excision of the primary tumor and treatment of all regional lymph node groups at highest risk for metastases by means of surgery or radiation therapy, depending on the clinical circumstances. Selective lymph node dissection can be performed along with wide excision of the primary tumor at the time of the initial operation. Sentinel lymph node (SLN) biopsy may provide a low morbidity staging opportunity for this as in other diseases.¹⁷ For example, carcinomas of the oral cavity are treated with supraomohyoid neck dissection, and carcinomas of the oropharynx, the hypopharynx, and the larynx are treated with lateral neck dissection. If extranodal extension or the presence of multiple levels of positive nodes is confirmed by the pathologic findings, the patient should receive adjuvant bilateral neck radiation therapy for 4 to 6 weeks after operation.

Metastatic Adenocarcinoma

Adenocarcinoma in a cervical node most frequently represents a metastasis from the thyroid gland, the salivary glands, or the gastrointestinal (GI) tract. The primary tumor must therefore be sought through endoscopic and radiologic study of the bronchopulmonary tract, the GI tract, the genitourinary tract, the salivary glands, and the thyroid gland. Other possible primary sites include breast and pelvic tumors in women and prostate cancer in men.

If the primary site is controlled and the tumor is potentially curable, or if the primary site is not found and the neck disease is the only established site of malignancy, neck dissection is the appropriate treatment. Postoperative adjuvant radiation may also be considered. If the patient has thyroid cancer and palpable nodes, lateral neck dissection (levels II to V) and central neck dissection (level VI) are recommended.

Overall survival is low—about 20% at 2 years and 9% at 5 years—except for patients with papillary or follicular thyroid cancer, who have a good prognosis. Two factors associated with a better prognosis are unilateral neck involvement and limitation of disease to lymph nodes above the cricoid cartilage.

Metastatic Melanoma

If the patient has a thin melanoma (Breslow thickness < 1 mm; Clark level I, II, or III), full-thickness excision with 1 cm margins is adequate treatment for the primary site.

Patients with intermediate-thickness melanomas (Breslow thickness 1 to 4 mm; Clark level IV) should have a full-thickness excision with at least a 1.5 cm margin. These patients also have a definable risk of lymph node spread and thus should be concurrently staged with lymphatic mapping and SLN biopsy. All patients with intermediate-thickness melanomas and positive SLNs and all melanoma patients with palpable lymph nodes should undergo complete staging with full-body CT/PET scans. If no other disease is found, modified neck dissection should be performed to obtain optimal local disease control. Because these tumors may metastasize to nodes in the parotid region, superficial parotidectomy is often included in the neck dissection, particularly in the case of melanoma located on the upper face or the anterior scalp. Consultation with a medical oncologist is indicated for all patients with intermediate-thickness or thick (Breslow thickness > 4 mm; Clark level V) melanomas; immunotherapy or chemotherapy may be considered. Radiation therapy is often considered in patients with extensive local or nodal disease following adequate surgical resection.

Metastasis from an Unknown Primary Malignancy

Management of patients with an unknown primary malignancy is challenging for the surgeon. It is helpful to

know that when cervical lymph nodes are found to contain metastatic squamous cell carcinoma, the primary tumor is in the head and neck about 90% of the time. Typically, such patients are found to have squamous cell carcinoma on the basis of FNA of an abnormal cervical lymph node; this finding calls for an exhaustive review of systems and a detailed physical examination of the head and neck.

If no primary tumor is identified, the patient should undergo endoscopic evaluation of the nasopharynx, the hypopharynx, the esophagus, the larynx, and the tracheobronchial tree under general anesthesia. Biopsies of the nasopharynx, the tonsils, and the hypopharynx often identify the site of origin (although there is some debate on this point). If the biopsies do not reveal a primary source of cancer, the preferred treatment is unilateral neck dissection, followed by radiation therapy directed toward the neck, the entire pharynx, and the nasopharynx. In 15 to 20% of cases, the primary cancer is ultimately detected. Overall 5-year survival in such cases ranges from 25 to 50%.

If a malignant melanoma is found in a cervical lymph node but no primary tumor is evident, the patient should be asked about previous skin lesions, and a thorough repeat head and neck examination should be done, with particular attention to the scalp, the nose, the oral cavities, and the sinuses. An ophthalmologic examination is also required. If physical examination and radiographic studies find no evidence of metastases, modified neck dissection should be performed on the involved side.

Metastatic adenocarcinoma in a cervical lymph node with no known primary tumor is discussed elsewhere [see

Metastatic Adenocarcinoma, *above*]. The most common primary sites in the head and neck are the salivary glands and the thyroid gland. The possibility of an isolated metastasis from the breast, the GI tract, or the genitourinary tract must also be rigorously investigated. If no primary site is identified, the patient should be considered for protocol-based chemotherapy and radiation therapy, directed according to what the primary site is most likely to be in that patient.

CONGENITAL NECK MASS

Thyroglossal Duct Cyst

Thyroglossal duct cysts are remnants of the tract along which the thyroid gland descended

into the neck from the foramen cecum [see Figure 3]. They account for about 70% of all congenital abnormalities of the neck. Thyroglossal duct cysts may be found in patients of any age but are most common in the first decade of life. They may present as a lone cyst, a cyst with a sinus tract, or a solid core of thyroid tissue. They may be so small as to be barely perceptible, as large as a grapefruit, or anything in between. Thyroglossal duct cysts are almost always found in the midline, at or below the level of the hyoid bone; however, they may be situated anywhere from the base of the

Figure 3 The course of the thyroglossal duct from the foramen cecum to the pyramidal lobe of the thyroid gland. The operative treatment of thyroglossal duct abnormalities includes removal of the central portion of the hyoid bone to ensure complete tract removal, thus limiting the risk of recurrence.

tongue to the suprasternal notch. They occasionally present slightly lateral to the midline and are sometimes associated with an external fistula to the skin of the anterior neck. They are often ballotable and can usually be moved slightly from side to side but not up or down; however, they do move up and down when patients swallow or protrude the tongue.

Thyroglossal duct cysts must be differentiated from dermoid cysts, lymphadenopathy in the anterior jugular chain, and cutaneous lesions (e.g., lipomas and sebaceous cysts). Operative treatment is almost always required, not only because of cosmetic considerations but also because of the high incidence of recurrent infection, including abscess formation. About 1% of thyroglossal duct cysts contain cancer; papillary cancer is the neoplasm most commonly encountered, followed by squamous cell carcinoma. About 25% of patients with papillary thyroid cancer in thyroglossal duct cysts have papillary thyroid cancer in other parts of the thyroid gland as well. About 10% have nodal metastases, which in some cases are bilateral.

Branchial Cleft Cyst

Branchial cleft cysts are vestigial remnants of the fetal branchial apparatus from which all neck structures are derived. Early in embryonic development, there are five branchial arches and four grooves (or clefts) between them. The internal tract or opening of a branchial cleft cyst is situated at the embryologic derivative of the corresponding pharyngeal groove, such as the tonsil (second arch) or the piriform sinus (third and fourth arches). The second arch is the most common area of origin for such cysts. The position of the cyst tract is also determined by the embryologic relation of its arch to the derivatives of the arches on either side of it.

The majority of branchial cleft cysts (those that develop from the second, third, and fourth arches) tend to present as a bulge along the anterior border of the sternocleidomastoid muscle, with or without a sinus tract. Branchial cleft cysts may become symptomatic at any age, but most are diagnosed in the first two decades of life. They often present as a smooth, painless, slowly enlarging mass in the lateral neck. Frequently, there is a history of fluctuating size and intermittent tenderness. The diagnosis is more obvious when there is an external fistulous tract and there is a history of intermittent discharge. Infection of the cyst may be the reason for the first symptoms.

Treatment consists of complete surgical removal of the cyst and the sinus tract. Any infection or inflammation should be treated and allowed to resolve before the cyst and the tract are removed.

Cystic Hygroma (Lymphangioma)

A cystic hygroma is a lymphangioma that arises from lymph channels in the neck. Almost always, this condition is first noted by the second year of life; on rare occasions, it is first diagnosed in adulthood. A cystic hygroma may present as a relatively simple thin-walled cyst in the floor of the mouth or may involve all the tissues from the floor of the mouth to the mediastinum. About 80% of the time, there is only a painless cyst in the posterior cervical triangle or in the supraclavicular area. A cystic hygroma can also occur, however, at the root of the neck, in the angle of the jaw

(where it may involve the parotid gland), and in the midline (where it may involve the tongue, the floor of the mouth, or the larynx).

The typical clinical picture is of a diffuse, soft, doughy, irregular mass that is readily transilluminated. Cystic hygromas look and feel somewhat like lipomas but have less well-defined margins. Aspiration of a cystic hygroma yields straw-colored fluid. They may be confused with angiomas (which are compressible), pneumatoceles from the apex of the lung, or aneurysms. They can be distinguished from vascular lesions by arteriography. On occasion, a cystic hygroma grows suddenly as a result of an upper respiratory tract infection, infection of the hygroma itself, or hemorrhage into the tissues. If the mass becomes large enough, it can compress the trachea or hinder swallowing.

In the absence of pressure symptoms (i.e., obstruction of the airway or interference with swallowing) or gross deformity, cystic hygromas may be treated expectantly. They tend to regress spontaneously; if they do not, complete surgical excision is indicated. Excision can be difficult because of the numerous satellite extensions that often surround the main mass and because of the association of the tumor with vital structures such as the cranial nerves. Recurrences are common; staged resections for complete excision are often necessary.

Vascular Malformation (Hemangioma)

Hemangiomas are usually considered congenital because they either are present at birth or appear within the first year of life. A number of characteristic findings—bluish-purple coloration, increased warmth, compressibility followed by refilling, bruit, and thrill—distinguish them from other head and neck masses. Angiography is diagnostic but is rarely indicated.

Given that most of these congenital lesions resolve spontaneously, the treatment approach of choice is observation alone unless there is rapid growth, thrombocytopenia, or involvement of vital structures.

4 HEAD AND NECK DIAGNOSTIC PROCEDURES

*Donald J. Annino Jr, MD, DMD, and Laura A. Goguen, MD, FACS**

Head and neck diseases can be inflammatory, infectious, congenital, neoplastic, or traumatic. An accurate diagnosis is mandatory and is based on a detailed history and physical examination, as well as ancillary tests. After a detailed history, including the chief complaint, history of present illness, past medical history, current medications, allergies, social history including tobacco and ethanol use, and family history, is obtained, a physical examination should be done.

The physical examination of the head and neck is complicated by the close relationship of structures and the need to examine many of the structures through orifices. The entire mucosal surface of the head and neck needs be examined when evaluating for head and neck cancers. Once a detailed history and physical examination have been done, a differential diagnosis list is created. The correct diagnosis and treatment plan are arrived at with the use of diagnostic procedures including imaging and sampling of the tissue.

Anatomy

The regions of the head and neck are usually divided into the following areas: the ear, the nose and paranasal sinuses, the oral cavity, the pharynx, the larynx, the salivary glands, and the neck, including the thyroid [see *Figure 1*].

EAR

The ear is divided into three parts: the external, middle, and inner ear. The external ear is made of the pinna and external auditory canal. The pinna is the only part of the ear that grows after birth. It is composed of an irregular plate of fibrocartilage tightly covered by skin and a thin layer of subcutaneous tissue. The external auditory canal is a tortuous passage with an average length of 3.7 cm in an adult male. The canal has thicker skin overlying cartilage in the outer half. This skin also has hair and special glands that secrete cerumen. The inner portion of the canal is thin skin over bone. The tympanic membrane is the common wall between the external ear and the middle ear. It is semitranslucent, cone shaped, and concave laterally.

The middle ear is an air-filled chamber that has five bony walls. The sixth wall is the tympanic membrane. Within the middle ear are ossicles. It is connected to the nasopharynx by the eustachian tube. It runs downward and forward and is composed of a cartilaginous segment and a bony segment.

The inner ear is made up of a system of channels and chambers within the otic capsule. It has two parts anatomically and functionally: the vestibular labyrinth and the cochlear. The vestibular system is responsible for balance and the cochlear system for hearing.

Tumors of the ear may present with pain, discharge, decreased hearing, facial nerve involvement, and dizziness.

NOSE AND PARANASAL SINUSES

The external nose is made of two fused nasal bones and four alar cartilages. There are two nasal passages that are separated by a vertical septum composed of cartilage (antero-inferiorly) and bone (the thin perpendicular plate of the ethmoid bone and the vomer). The nose is lined with ciliated respiratory mucoperichondrium, which contains glands and mucus-secreting cells. The cribriform plate forms the roof of the nose, with the hard palate forming its floor. The lateral wall is a partition between the paranasal sinuses and the nasal passages. There are three turbinates on each lateral wall: superior, middle, and inferior. The inferior turbinate is the largest and most vascular. The turbinates divide the nasal passages vertically and create the superior, middle, and inferior meatuses.

There are four paranasal sinuses on each side. The frontal and sphenoid sinuses are midline and frequently are asymmetrical. The ethmoid and maxillary sinuses are placed laterally. The ethmoid sinus is considered the key sinus and can provide access to all the other sinuses [see *Figure 2*]. Its roof is the fovea ethmoidales, which, in conjunction with the cribriform plate, separates the anterior cranial vault from the nose. The sphenoid sinus is the most posterior sinus and has the internal carotid artery, optic nerve, second division of the trigeminal nerve, and vidian nerve all in close proximity.

The symptoms associated with nasal cavity tumors frequently do not occur early in the diseases because much of the nasal cavity and paranasal sinuses is air filled. This can also be a hard area to examine, and the symptoms are usually first attributed to more mundane conditions, such as allergies and sinusitis. The most common symptoms are facial pain, nasal obstruction, epistaxis, nasal discharge, decreased sense of smell, and changes to the orbit.

Oral Cavity

The limits of the oral cavity are the lips anteriorly and the anterior tonsil pillars and circumvallate papillae of the tongue posteriorly. The oral cavity is divided into the vestibules, which is the space between the teeth and cheek; the alveolar ridges, which are the teeth-bearing areas of the maxilla and mandible; the floor of the mouth; the retromolar trigone, which is the triangular area of gum and soft tissue immediately posterior to the lower molars; the buccal mucosa, which

* The authors and editors gratefully acknowledge the contributions of the previous authors, Adam S. Jacobson, MD, Mark L. Urken, MD, FACS, and Marita S. Teng, MD, to the development and writing of this chapter.

Figure 1 The anatomic structures of the head and neck are shown.

is the mucous membrane lining of the cheek; and the oral tongue, which is the anterior two thirds of the tongue. The posterior limit is the circumvallate papillae.

Salivary Glands

Salivary glands are subdivided into major and minor salivary glands. The major salivary glands consist of the parotid glands, submandibular glands, and sublingual glands. The parotid gland is the largest salivary gland. It is incompletely split by the facial nerve into deep and superficial lobes. The main duct runs horizontal to the zygoma on the lateral surface of the masseter and enters the oral cavity opposite the second maxillary molar. It has serous secretions with low mineral content. Approximately 80 to 85% of the neoplasms in the parotid are benign.

The submandibular gland is below the body of the mandible. It lies on the lateral surface of the mylohyoid muscle. The duct passes upward and medially to the anterior floor of the mouth. Its secretions are mixed serous and mucous, and it has a higher mineral content than the parotid gland. Neoplasms in the submandibular glands are more evenly split between malignant and benign.

The sublingual glands are located in the floor of the mouth and frequently have multiple ducts. The secretion is mucous.

Thousands of minor salivary glands are present throughout the oral cavity, pharynx, and epiglottis. Minor salivary gland neoplasms are usually malignant, with quoted rates around 75%.

Pharynx

The pharynx is an incomplete muscular tube from the base of the skull to the inlet of the esophagus. The pharynx is divided into three parts: the nasopharynx, oropharynx, and hypopharynx. The nasopharynx sits behind the nasal cavity, extending from the choanae to the inferior surface of the palate. Adenoid tissue and the eustachian tubes are present in the nasopharynx. Malignancies of the nasopharynx can present as nasal obstruction, epistaxis, tinnitus, headache, diminished hearing, and facial pain.

The oropharynx extends from the junction of the hard and soft palates and the circumvallate papillae to the valleculae. It includes the soft palate and uvula, base of the tongue, pharyngoepiglottic and glossoepiglottic folds, palatine arch

Figure 2 The paranasal sinuses are shown.

(which includes the tonsils and the tonsillar fossae and pillars), valleculae, and lateral and posterior oropharyngeal walls. Carcinomas of the oropharynx can present as pain, sore throat, dysphagia, and referred otalgia.

The hypopharynx extends from the superior border of the hyoid bone to the inferior border of the cricoid cartilage. It includes the piriform sinuses, hypopharyngeal walls, and postcricoid region (i.e., the area of the pharyngoesophageal junction). Malignancies of the hypopharynx can present as odynophagia, dysphagia, hoarseness, referred otalgia, and excessive salivation.

LARYNX

The larynx is subdivided into the supraglottis, glottis, and subglottis. It consists of a framework of cartilages that are held together by extrinsic and intrinsic musculature and lined with a mucous membrane that is topographically arranged into two characteristic folds (the false and true vocal cords). The larynx has the following basic functions: (1) to protect the lower airway; (2) to conduct air to the lungs; and (3) to allow vocalization. Neoplasms of the larynx can present as hoarseness, dyspnea, stridor, hemoptysis, odynophagia, dysphagia, and otalgia.

Supraglottis

The supraglottis extends from the tip of the epiglottis to the junction between respiratory and squamous epithelium on the floor of the ventricle (the space between the false and true cords). Carcinomas of the supraglottis can present as sore throat, odynophagia, dysphagia, and otalgia.

Glottis

The space between the free margin of the true vocal cords is the glottis. This structure is bounded by the anterior

commissure, true vocal cords, and posterior commissure. The most common symptom of carcinoma of the glottis is hoarseness.

Subglottis

The subglottis extends from the junction of squamous and respiratory epithelium on the undersurface of the true vocal cords (approximately 5 to 10 mm below the true vocal cords) to the inferior edge of the cricoid cartilage. The cricoid is the only complete cartilaginous ring in the airway; therefore, it is the only rigid area in the respiratory tree. The most common symptom of carcinoma of the subglottis is hoarseness.

NECK

The neck is divided into different compartments by fascia. The visceral compartment is in the midline and contains the larynx, pharynx, trachea, thyroid, parathyroid glands, recurrent laryngeal nerves, and cervical esophagus. The neurovascular compartment runs the entire length of the neck from the base of the skull to the esophageal inlet. It contains the carotid artery, internal jugular vein, vagus nerve, and jugular lymph nodes. There are two muscular compartments on each side of the neck. Neoplasms in the neck usually present as masses. Most commonly, they are painless. When malignant, they are usually metastatic from primary malignancies in the aerodigestive tract.

The thyroid gland performs a vital role in regulating metabolic function. It is susceptible to benign conditions (e.g., nodule, goiter, and cyst), inflammatory disease (e.g., thyroiditis), and malignancies. Additionally, congenital anomalies of the thyroid, such as a thyroglossal duct cyst, can present later in life. Thyroid lesions can present as pain, hoarseness, dyspnea, or dysphagia.

On the posterior aspect of the thyroid gland reside the four parathyroid glands. These glands play a vital role in maintaining calcium balance. Parathyroid adenomas and, rarely, carcinomas can develop.

Clinical Evaluation

The diagnostic approach to the upper aerodigestive tract begins with a thorough history, starting with a detailed evaluation of the chief complaint. Once a complete history of the chief complaint has been obtained, the physician should elicit a more comprehensive general medical history from the patient, including pertinent past medical history, past surgical history, medications, allergies, social history (tobacco, ethanol, and intravenous drug use), and family history.

The next step is to perform a comprehensive physical examination. This begins with a thorough inspection of the entire surface of the head and neck. The examination should proceed in an orderly fashion. The exact order is not important, but examiners should determine the order with which they are most comfortable and not deviate from that order. This way, they are unlikely to skip an anatomic area. The mucosal surfaces of the aerodigestive tract are inspected. Endoscopic evaluation of the upper aerodigestive tract is crucial in establishing a definitive diagnosis. The equipment used consists of both rigid and flexible laryngoscopes, bronchoscopes, and esophagoscopes. Many of these techniques can be performed in the office setting, providing the surgeon with an array of methods for gaining the information necessary for a working diagnosis and, in some cases, for performing a therapeutic intervention [see Figure 3]. Operative endoscopy is performed to obtain a definitive diagnosis, to stage tumors, and to rule out synchronous lesions. There is no substitute for a thorough examination and biopsy of a lesion with the patient under general anesthesia. Regardless of the endoscopic method used, an adequate biopsy specimen must be obtained for a histologic diagnosis.

An accurate history and a careful physical examination of the head and neck, including the mucosal surfaces, are the most important steps in evaluating a lesion in this part of the body; this clinical evaluation usually provides only a working diagnosis. The head and neck surgeon must then proceed in a stepwise fashion to further clarify the diagnosis and, in the case of a neoplasm, to perform an accurate staging.

Radiographic techniques allow the head and neck surgeon to visualize the mass and determine its characteristics (i.e., to differentiate between solid and cystic lesions), as well as its anatomic associations. Ultrasonography, magnetic resonance imaging (MRI), computed tomography (CT), and dual-modality positron emission tomography (PET)/CT each provide a unique view of the pathology in question and thereby help narrow the differential diagnosis. Acquisition of a tissue specimen for cytologic or histologic analysis, or both, is the next step. Fine-needle aspiration (FNA) is often used at this stage in the workup provided that the location of the mass lends itself to a safe procedure. If the lesion is located deep in the neck near vital structures, image-guided FNA can be attempted before resorting to an open biopsy. If the lesion is on a mucosal surface of the upper aerodigestive tract, an endoscopic biopsy is performed. Often panendoscopy is performed at this point to accurately map the lesion, obtain

Figure 3 Otolaryngology clinic office space with needed equipment, including an examination chair, a headlight, and a fiberoptic rhinolaryngoscope.

a tissue specimen, and, in patients with cancer, assess the rest of the upper aerodigestive tract for a synchronous primary tumor.

After a histologic diagnosis has been made and correlated with imaging, the patient and the physician can have a comprehensive discussion of the pathology, the stage of the disease, and the selection of therapy.

NOSE

Anterior Rhinoscopy

Anterior rhinoscopy is the examination of the nasal cavities with the use of a nasal speculum [see Figure 4]. The speculum is used to spread the ala. When done, the speculum should touch only the parts that are covered with skin. Resting the speculum on the nasal mucosa is painful. Anterior rhinoscopy is best done before and after topical vasoconstriction of the nasal mucosa. A good coaxial light source is needed. The more anterior portions of the nasal cavity are most readily examined.

Posterior Rhinoscopy

Posterior rhinoscopy is used to examine the posterior portion of the nasal cavity and, more importantly, the

Figure 4 Shown is an assortment of nasal specula.

nasopharynx. It is done with a small-angled mirror placed posterior to the palate and uvula. The tongue should be depressed using a tongue blade with the other hand. This examination is limited at times by the patient's gag reflex and the presence of enlarged adenoids.

Rigid Nasal Endoscopy

Rigid nasal endoscopy offers a superior view of the nasal cavity. Topical anesthesia and vasoconstriction are required for a good examination. The image is magnified, and deeper structures are better visualized than with anterior rhinoscopy. The endoscopes come in a variety of lens angles (0, 30, and 90 degrees). This allows inspection of structures that may be blocked from direct line of site. A more complete examination of both the anterior and posterior nasal cavities and nasopharynx is obtained than with anterior and posterior rhinoscopy. Rigid nasal endoscopy has become the examination of choice for a through nasal evaluation.

LARYNX AND PHARYNX

Indirect Laryngoscopy

Indirect laryngoscopy is used to examine the larynx, oropharynx, and hypopharynx. It is done in the clinic under topical or no anesthesia. An angled mirror is used, and the patient needs to be sitting upright with the neck straight and the head thrust slightly forward [see Figure 5]. A bright coaxial light source is used. The patient should relax and breathe

Figure 5 Shown is a laryngeal mirror, which is used for indirect laryngoscopy.

deeply and rhythmically, as if panting like a dog. The non-dominant hand of the examiner grasps the patient's tongue with gauze. The mirror is warmed and placed gently against the soft palate. To optimize the view, the examiner should ask the patient to say "ee." This technique can be performed rapidly and is inexpensive.

Flexible Laryngoscopy

Flexible laryngoscopy is also referred to as flexible rhinolaryngoscopy [see Figure 6]. It has become the most common way to examine the nasopharynx, oropharynx, hypopharynx, and larynx and is superior to indirect laryngoscopy. It allows better visualization and assessment of the structures, and since the tongue is not grasped, it allows better assessment of how structures function. The procedure is better tolerated by the patient, with less gagging. It has the disadvantage of requiring more expensive equipment than indirect laryngoscopy. Topical anesthesia is used. Most commonly, an anesthetic and a decongestant are sprayed into the nasal cavity prior to the procedure. The passage of the scope is best tolerated passing just inferior to the middle turbinate. If the patient has a deviated septum, the side with less obstruction is used.

Fiberoptic examinations in the clinic setting are not tolerated by all patients. Even if this examination is tolerated, an exact diagnosis frequently is not reached or a lesion is seen that cannot be biopsied in the clinic. It is recommended that the patients undergo an examination under anesthesia. This is done to look for an occult synchronous tumor and to more accurately examine and map the known tumor. The advantages of doing this under anesthesia are that it is better tolerated by the patient (gagging is eliminated) and allows deeper digital palpation and biopsies as needed. The disadvantage is that it requires general anesthesia and its possible complications as well as the complications of the procedure.

Direct Laryngoscopy

Direct laryngoscopy requires general anesthesia and therefore is done in the operating room. It is done with hollow, metal, rigid tubes [see Figure 7]. The laryngoscopes used by otolaryngologists differ from those used by anesthesiologists. They are straight and tubular and have distal lighting. There

Figure 6 A small-caliber flexible laryngoscope is used for rhinolaryngoscopy.

Figure 7 Shown are (a) normal vocal folds directly visualized via (b) a rigid laryngoscope.

are many different laryngoscopes. The sides of the laryngoscope hold surrounding soft tissue out of the way, allowing uninterrupted direct inspection of pharyngeal and laryngeal structures. The teeth are protected with a guard, and the structures in the oral cavity, pharynx, and larynx are all examined. It is best to become accustomed to doing this procedure in a specific order so that it becomes routine and lesions will not be missed. With the use of general anesthesia, palpation of the structures and a lesion can be done. The examination can be improved with suspension of the laryngoscope from a Mayo stand or the use of other suspension devices to allow the surgeon's hands to be free to perform procedures. Increased magnification is possible with the added use of a microscope. This is particularly useful when examining laryngeal lesions and is referred to as suspension microlaryngoscopy. A laser can also be used if needed.

ESOPHAGUS

Esophagoscopy plays an important role in the evaluation of patients with dysphagia, odynophagia, caustic ingestion, trauma, ingested foreign bodies, suspected anomalies, and upper aerodigestive tract malignancies. This procedure may be performed with either a flexible or a rigid scope.

Flexible Esophagoscopy

Flexible esophagoscopy is a diagnostic tool used to examine the esophagus and stomach. It is not well suited to visualizing the pharynx and is usually used in an outpatient setting with sedation and topical anesthesia. It is easier to perform than rigid esophagoscopy in patients who are elderly or have limited neck mobility, short, thick necks, and/or a limited mouth opening. The examination is usually done in the lateral decubitus position with the neck flexed. Air insufflation is important to completely visualize the mucosal surfaces. Tissue sampling is performed with a cup forceps through a working channel or by obtaining a brush biopsy. An endoscopic ultrasound probe can be passed to help define the extent of cancer of the esophagus. It is particularly useful to see the depth to which a tumor has invaded into the wall of the esophagus. If a lesion is found within the esophagus, its location is measured in centimeters from the teeth.

Rigid Esophagoscopy

Rigid esophagoscopy has been used for more than a century [see Figure 8]. It is used to diagnose cancer and remove foreign bodies. Unlike flexible esophagoscopy, it needs to be done under general anesthesia. The esophagoscope is a hollow metal tube of varying lengths and widths. The patient is placed supine and the maxillary teeth are protected with a mouth guard. The scope is passed transorally under direct visualization down the right side of the oral cavity and pharynx. If resistance is met, the scope should never be forced. There is a greater chance of perforation than with a flexible scope. As the scope is advanced, the lumen of the esophagus is kept in the center of the field of vision. The lumen has the appearance of a rosette. When advancing the scope, the left thumb is used. The right hand helps direct the scope and is used to pass instruments through its lumen. With rigid esophagoscopy, the removal of the scope is as important, if not more so, than inserting it. Removal allows better visualization of the mucosal surface as it slips over the tip of the instrument as it is removed.

TRACHEA AND LUNGS

Bronchoscopy is the technique of visualizing the trachea and lungs for both diagnostic and therapeutic reasons. Two basic forms of bronchoscopes are available: rigid and flexible. Each has its own advantages and disadvantages.

Rigid Bronchoscopy

The use of rigid bronchoscopy began in the 19th century with Killian. A rigid bronchoscope is a hollow, metal tube that is available in differing widths and lengths [see Figure 9].

Figure 8 Shown is a rigid esophagoscope.

Figure 9 (a) Rigid bronchoscopes incorporate stainless steel tubes of varying lengths and diameters. The beveled distal end of this Hopkins bronchoscope facilitates mobilization of the epiglottis during intubation; the side ports permit ventilation and use of suction catheters. (b) Illumination is provided by fiberoptic rods that are inserted into the bronchoscope.

It is used to examine the trachea and lungs and requires general anesthesia. It is used to remove foreign bodies and to diagnose and biopsy tumors and is better than flexible bronchoscopes for evaluation of large-volume hemoptysis because it allows suctioning and instruments to be used together. The patient is under general anesthesia with the neck hyperextended.

The bronchoscope is passed into the trachea either directly or through a slotted laryngoscope. Once in the airway, ventilation is usually done through a port on the scope. Venturi jet ventilation is also possible through a rigid bronchoscope. The entire trachea and main bronchi of both lungs are easily examined. Bronchial lavage is also possible.

Flexible Bronchoscopy

In the 1970s, Ikeda introduced flexible bronchoscopy. It is usually performed under sedation and is more common than rigid bronchoscopy. The instrument is thinner and longer than a rigid scope. There is a working channel that allows passage of biopsy forceps and brushes and lavage.

Panendoscopy

When visualization of the entire mucosal surface of the aerodigestive tract is needed, then panendoscopy is performed. Panendoscopy is the term used when direct laryngoscopy (with or without microscopic assistance), esophagoscopy, and bronchoscopy are done in the same setting.

Biopsy

After a thorough physical examination and history, tissue sampling should be considered if a lesion has been present for more than 3 to 4 weeks. To make a diagnosis, an open biopsy is not immediately indicated. Other methods are available to help obtain tissue and make a diagnosis. However, a biopsy is not recommended until after the history and physical examination have been done and appropriate imaging has been obtained. Imaging is important prior to a biopsy because the biopsy may cause a distortion of the tissue, such as occurs when a hematoma develops.

When a biopsy is indicated to establish a diagnosis for a neck mass or lesion, the options include FNA, a core biopsy, and an open biopsy. FNA offers the advantages of being simple and quick and can be done in the clinic.

FNA is possible for lesions that can be palpated. A thin-gauge needle is passed into the lesion, allowing a small number of cells to be sampled. It is a safe procedure that can be done under local or no anesthesia. It has not been shown to have an increased risk of seeding of the tumor spread along its tract. However, there is a risk of sampling error. This occurs if the needle does not collect a representative sample from the lesion. In reality, the test has a high sensitivity and specificity. The benefits of FNA include the rapid availability of results.

To optimize sampling, FNA can be done under guidance with CT or ultrasonography. The use of imaging allows direct visualization of the biopsy and therefore increases the likelihood of obtaining an accurate sample.

The procedure is performed with a thin-gauge needle such as a 23-gauge needle. The needle is attached to a 20 mL syringe, which allows negative pressure to be generated [see Figure 10]. Multiple passes are made through the lesion prior to removing the needle. Just before the needle is removed from the skin, any negative pressure in the syringe is released and the needle is withdrawn. If a cyst is encountered, it should be completely evacuated and the fluid sent for cytologic analysis. Ideally, for FNA, there should be minimal to no fluid or tissue in the syringe. The cells should be in the needle. The sample is then placed on a glass slide. A smear is made by laying another glass slide on top of the drop of fluid and pulling the slides apart to spread the fluid. Fixative spray is then applied. Alternatively, wet smears are placed in 95% ethyl alcohol and treated with the Papanicolaou technique and stains.

When the lesion is not easily palpated or is close to a delicate structure, FNA may need to be done under imaging. The most common imaging techniques used are ultrasonography and CT. When ultrasonography is used, it allows real-time imaging of the needle's passage. This results in an accurate trajectory and avoidance of vital structures. It also provides an image of the mass, allowing its characterization as solid, cystic, or heterogeneous. With cystic or complex masses, the tip of the needle can be placed into the wall to increase specimen yield.

CT guidance also provides visualization of the needle as it is passed through the tissue and into the underlying mass. It has the disadvantage of requiring ionizing radiation.

Core Biopsy

A core biopsy is a percutaneous biopsy done with a large-bore needle. The needle has a cutting tip and a hollow core. The area is infiltrated with local anesthesia prior to the needle being passed. The procedure can be done with image

Figure 10 A 20 mL syringe with a 23-gauge needle attached. The syringe is mounted in a handle to help allow creation of negative pressure.

guidance if needed. It has the disadvantage of causing more bleeding and has an increased risk of seeding the tumor along the needle tract. For most lesions in the neck, FNA is usually the first choice.

Open Biopsy

An open biopsy is indicated when a needle biopsy or core biopsy is unable to give a diagnosis. This can be done in either the clinic or, more commonly, in the operating room. Whenever possible, open biopsy is usually done after other techniques have not yielded a diagnosis. It has the greatest chance of seeding the tumor along the path of the biopsy.

Imaging

Imaging studies are important in the workup of patients with head and neck complaints. This is true because direct visualization of many structures is difficult because most of the structures are examined through orifices. The most common studies ordered are a barium swallow, CT, MRI, ultrasonography, and dual-modality PET with CT.

ULTRASONOGRAPHY

Ultrasonography offers many advantages. It is inexpensive, offers real-time imaging, and is performed without radiation exposure. Ultrasonography is particularly helpful in differentiating between solid and cystic masses. It allows evaluation of surrounding structures such as blood vessels. It is an excellent tool to follow masses to assess for changes in the size or character of the structure. It can also be used to help guide cytologic evaluation with FNA.

Barium Swallow

A barium swallow is used to examine the esophagus and, to a lesser extent, the stomach. Barium sulfate is swallowed and is used to identify tumors, ulcers, diverticula, and strictures. It is done under fluoroscopy to be able to follow the dynamic passage of the barium through the esophagus and stomach.

Computed Tomography

CT of the neck with contrast is the most common test performed to evaluate a mass in the head and neck. It allows

evaluation of the primary tumor and regional metastasis. It is usually used as part of the workup for head and neck malignancies and for surveillance posttreatment.

Magnetic Resonance Imaging

MRI results in superior evaluation of soft tissue compared with CT and does so without ionizing radiation. Instead, its images are attributable to a strong magnetic field that aligns the nuclear magnetization of hydrogen atoms in water. The examination is more difficult for some patients to tolerate compared with CT. The machine can make patients feel more claustrophobic and is noisier during the procedure. It also has the disadvantage that patients with implanted ferromagnetic foreign material are not able to go into the magnetic field. MRI is not as accurate for calcium structures such as bone and teeth.

Positron Emission Tomography/Computed Tomography

PET is a study that measures tissue metabolic activity by using a radioactive tracer. The tracer is fluorodeoxyglucose (FDG), an analogue of glucose. FDG is short acting with a half-life of 110 minutes. The scan works because neoplastic cells have a higher rate of glycolysis; therefore, the tracer is localized in the tissue. Unfortunately, tracer localization is not specific for neoplastic disease and can occur with inflammatory processes as well. Muscle activity will also result in increased uptake of the FDG. The scan is also limited by the inability to identify neoplasms that are smaller than 3 to 4 mm. In this situation, the amount of FDG concentrated is not large enough to stand out from the surrounding structures. The dual-modality scan of PET/CT has, for the most part, replaced the PET scan alone. Performing coregistered scans allows the metabolic activity from the PET scan to be more accurately correlated with the anatomic detail of the CT. PET/CT is most useful in head and neck oncology to look for unknown primary tumors, second primary tumors, and metastatic disease, both regional and distant. In the era of chemoradiotherapy, PET/CT has been used posttreatment to assess for response to treatment. This is most accurately done 2 to 3 months after treatment because the inflammation must resolve first.

5 ORAL CAVITY PROCEDURES

Carol R. Bradford, MD, FACS, and Mark E.P. Prince, MD, FRCSC

Preoperative Evaluation

Oral cavity procedures are commonly performed to treat malignancies. Tumors should be assessed preoperatively to allow accurate staging of the disease and to facilitate planning of definitive treatment. In most cases, an examination under anesthesia with endoscopy and biopsy is required to stage the primary tumor and to look for synchronous second primary tumors. Except in the case of very superficial lesions, computed tomography (CT) plays an important role in preoperative planning. In selected cases, plain radiographs (e.g., Panorex views) may be useful in evaluating the mandible. When the lesion is located in the tongue, magnetic resonance imaging (MRI) may provide additional information about the extent of the primary tumor.

Wide surgical margins are necessary for adequate treatment of primary squamous cell carcinoma of the head and neck. A margin of 1 to 2 cm should be achieved whenever possible, ideally with frozen-section control. Current evidence clearly indicates that overall patient outcome improves when clear margins are obtained.

Nodal metastases are common with oral cavity tumors. Accordingly, patients should be assessed for cervical adenopathy both clinically and radiographically. A chest x-ray should be obtained in all cases. CT or MRI can provide valuable information regarding the nodal status of the neck. In patients with advanced disease, a more extensive search for distant metastases should be conducted, including a CT scan of the chest. In some circumstances, combining CT with positron emission tomography (PET) may be useful.

Operative Planning

Surgical management of the neck is an evolving field. In general, if the risk of occult metastasis is greater than 20 to 25%, a selective neck dissection is recommended, particularly if postoperative radiation therapy is not planned. Whenever there is clinical evidence of nodal disease, treatment of the neck must be included in operative planning.

The oral cavity is a major component of a number of important functions, including speech and swallowing. Reconstruction of the anticipated surgical defect must be carefully planned to achieve the best results. Several basic considerations must be kept in mind. Tongue mobility and sensation must be maintained to the extent possible. Maintenance of mandibular continuity (especially in the anterior segment of the mandible) is vital for ensuring postoperative oral competence. Separation of the nasal cavity from the oral cavity is critical for the oral phase of swallowing and speech. Maintenance of the gingivobuccal and gingivolabial sulcus is important for oral function and the fitting of dentures.

As a rule, oral cavity defects should be closed primarily whenever possible. Primary closure has the advantage of

using sensate tissue similar in form to the tissue that was excised. With experience and careful judgment, the surgeon can usually determine when a defect is too large for primary closure or when primary closure is likely to cause distortion and tethering of adjacent tissues and result in a significant functional disturbance. In such cases, a flap reconstruction must be considered. In select cases, pedicled flaps may be appropriate. Often, particularly with larger or more complicated defects, free flaps provide the best reconstructive result. Free tissue reconstruction has the advantage of allowing the surgeon to reconstruct the defect with the exact tissue components that were excised, including bone and skin. In addition, free flaps can be reinnervated to achieve a sensate reconstruction.

If the planned surgical procedure involves resection of part of the maxilla or the mandible, appropriate dental consultation should be obtained. If a postoperative splint, obturator, or dental prosthesis is to be placed, it is critical that dental impressions be obtained before operation. Thyroid function should be tested in all patients who have a history of radiation therapy to the neck to confirm that they are euthyroid.

In cooperative patients, small primary lesions of the oral cavity can sometimes be excised with local anesthesia; however, general anesthesia with adequate relaxation is required in the majority of cases. The route of intubation must be carefully considered for each patient. When the planned resection is extensive and when significant postoperative edema is anticipated, a tracheostomy should be performed. Patients with bulky lesions should undergo tracheostomy under local anesthesia before general anesthesia is induced. When a tracheostomy is not planned, nasotracheal intubation is often desirable.

When the excision is limited to the oral cavity, perioperative antibiotics are generally unnecessary. When a graft, a flap, or packing is employed, however, perioperative intravenous administration of antibiotics is advisable. In all cases in which the neck is entered, perioperative antibiotics are recommended. The oral cavity can be prepared preoperatively with chlorhexidine and a toothbrush.

A nasogastric feeding tube should be inserted whenever it is believed that the patient may have a problem maintaining oral nutrition postoperatively. Patients who undergo primary closure or split-thickness skin grafting or whose surgical wound is allowed to heal by secondary intention may be allowed clear liquids in 24 to 48 hours and a pureed diet by postoperative day 3; they can often tolerate a soft diet within 1 week. Patients who undergo flap reconstruction will have to be fed via a nasogastric tube until they have healed to the point where they can resume oral intake.

Patients should be advised to maintain oral hygiene postoperatively by means of frequent irrigation and rinses with either normal saline or half-strength hydrogen peroxide.

Teeth may be gently cleaned with a soft toothbrush until healing has occurred.

Anterior Glossectomy

OPERATIVE PLANNING

Either orotracheal or nasotracheal intubation may be appropriate, depending on the surgical approach and the extent of the planned resection. A tracheostomy should be performed whenever significant postoperative swelling or airway compromise is anticipated.

The depth of the excision and the size of the anticipated defect determine the optimal reconstructive approach. Defects that connect to the neck, unless they are small and can easily be closed primarily, usually necessitate creation of a flap for optimal reconstruction. When the excision extends down to the underlying musculature but there is no connection to the neck, a skin graft may be used. If a postoperative dental splint is planned to hold a skin graft in place, a dental consultation must be obtained before operation.

The patient should be supine in a 20° reverse Trendelenburg position. Turning the table 180° may facilitate access and positioning for the surgeon.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

Small anterior lesions up to 2 cm in diameter may be approached transorally, as may certain carefully selected larger lesions. Exposure of the tongue is usually achieved with the help of an appropriately sized bite block; alternatively, a specialized retractor (e.g., a Molt retractor) may be used. Retraction of the tongue is facilitated by the use of a piercing towel clip or a heavy silk suture placed through the tip of the tongue.

Access to posterior lesions and most larger lesions is obtained by performing a mandibulotomy through a lip-splitting incision [see Figure 1]. A stair-step incision is made in the lip and extended downward straight through the mentum, and a Z-plasty is done at the mental crease. Alternatively, the incision may be carried around the mental subunit.

The mandibular periosteum is elevated and a plate contoured to the mandible before the mandible is divided; this measure ensures exact realignment of the cut ends of the mandible. When possible, the mandibulotomy should be made anterior to the mental foramen to preserve sensation throughout the distribution of the mental nerve. Repair of the mandibulotomy is greatly facilitated by making a stair-step or chevron-type mandibulotomy [see Figure 2]. A paralingual mucosal incision is made to allow retraction of the mandible and exposure of the posterior oral cavity.

As an alternative, a visor flap may be created [see Figure 3]. Such a flap allows the surgeon to avoid making a lip-splitting incision and provides adequate exposure of small lesions of the anterior oral cavity; however, it is inadequate for exposure of lesions posterior to the middle third of the tongue or in the area of the retromolar trigone. Furthermore, creation of a visor flap results in anesthesia of the lower lip because of the necessity of dividing both mental nerves.

Figure 1 Anterior glossectomy. A lip-splitting incision is made that extends downward straight through the mentum.

To create a visor flap, an incision is made from mastoid to mastoid along a skin crease in the neck, with care taken to remain below the marginal mandibular nerves. The skin flap is elevated in the subplatysmal plane to the level of the mandible. The marginal mandibular nerves are preserved. The flap is elevated from the lateral surface of the mandible, and the two mental nerves are divided. An incision is made in the oral cavity mucosa along the gingivolabial sulcus and

Figure 2 Anterior glossectomy. A stair-step mandibulotomy is made.

Figure 3 Anterior glossectomy. As an alternative to a lip-splitting incision with mandibulotomy, a visor flap may be employed for exposure.

continued so that it connects to the skin incision. The flap is then retracted superiorly to expose the anterior mandible and the oral cavity.

Step 2: Resection

The excision should include a generous mucosal margin around the visible lesion. A significant amount of the tongue musculature surrounding the lesion should be resected as well. Palpation of the lesion is critical for obtaining adequate deep surgical margins.

Resection may be performed with a monopolar electrocautery, with the cutting current used to incise the mucosa and the coagulation current used to cut the muscle. Alternatively, resection may be performed with a scalpel and scissors. Hemostasis is achieved with a monopolar or bipolar electrocautery. Larger vessels are ligated with chromic catgut or Vicryl ties.

Lesions of the lateral tongue should be wedge-excised in a transverse (rather than horizontal) fashion to facilitate closure and enhance postoperative function. With larger lesions, for which either flap reconstruction or healing by secondary intention is typically indicated, the shape of the defect is contoured so as to obtain wide margins around the lesion, and the flap is designed to fill the contoured defect.

Step 3: Reconstruction

After negative margins are confirmed by frozen-section examination, repair of the surgical defect is initiated. Careful preoperative assessment of the anticipated defect lays the groundwork for optimal reconstruction. Many defects can be either repaired primarily or allowed to heal by secondary intention. Free tissue transfer is an excellent reconstructive option in many cases, allowing the maintenance of tongue mobility and the separation of the tongue from the mandible and making sensate reconstruction possible.

In many patients with wedge-excised lateral tongue lesions, primary closure of the defect yields good results. The deep muscle is carefully reapproximated with long-lasting absorbable sutures. The mucosa is also closed with absorbable sutures. Care should be taken not to strangulate tissues by making the sutures too tight. When complete primary closure is not possible or desirable, the tongue may be allowed to granulate and heal by secondary intention. Split-thickness skin grafts, although useful for relining the floor of the mouth, generally do not take well on the tongue.

For large defects of the tongue and those involving the floor of the mouth, flap reconstruction is appropriate. Defects that connect to the neck, unless they are small and can be closed primarily, should also be closed with a flap. Free tissue transfer is frequently the optimal reconstructive approach. Free fasciocutaneous flaps from the radial forearm, the anterior lateral thigh, or the lateral arm are well suited to reconstruction in this area. Pedicled flaps (e.g., myocutaneous flaps from the pectoral muscle) are also used in this setting but are bulkier and harder to contour to the defects.

If a mandibulotomy was made, it is repaired with the previously contoured plate. The lip-splitting incision is closed in three layers (mucosa, muscle, and skin). Great care must be taken to ensure accurate realignment of the vermilion border and the orbicularis oris muscle.

Alternative Procedure: Laser Vaporization

Very superficial and premalignant lesions of the tongue may be vaporized by using a CO₂ laser. The desired depth of tissue destruction for leukoplakia is approximately 1 to 2 mm.

TROUBLESHOOTING

Larger excisions may lead to airway edema. Whenever this possibility is a concern, a tracheostomy should be performed. A single intraoperative dose of steroids may reduce postoperative tongue edema without adversely affecting wound healing. Using a stair-step incision for the lip-splitting incision facilitates accurate reapproximation of the vermilion border. Excessive tongue movement may result in dehiscence of the closure. Voice rest for 3 to 5 days after operation may be beneficial.

POSTOPERATIVE CARE

Patients who undergo primary closure of the tongue may begin a fluid diet on the day after operation; they should remain on a liquid diet for 7 to 10 days. Patients who undergo skin grafting may also begin a liquid diet on postoperative day 1. If a flap was used to close the defect or if there is some question whether the patient will be capable of adequate oral intake, a nasogastric feeding tube should be inserted and maintained until the suture lines heal.

Bolster dressings may be removed and skin grafts inspected after 7 to 10 days. Patients with skin grafts should stay on a soft diet for 2 weeks. If a tracheotomy was performed, the patient may be decannulated when postoperative edema has settled.

Meticulous and frequent oral hygiene is essential. Mouth rinses and irrigation with normal saline or half-strength hydrogen peroxide should be done at least four times a day and after every meal. Teeth may be gently cleaned with a soft toothbrush.

COMPLICATIONS

The main complications of anterior glossectomy are as follows:

1. Injury to the lingual nerve, which causes numbness and loss of the sense of taste in the ipsilateral tongue
2. Injury to the submandibular and sublingual gland ducts, which causes obstruction of the glands, pain and swelling, and possibly ranula formation
3. Injury to the hypoglossal nerve, portions of which are resected with the lesion. Injury to the main trunk of this nerve leads to paralysis and atrophy of the remaining ipsilateral tongue.
4. Tethering and scarring of the tongue, which can lead to difficulties with speech and swallowing. This problem can usually be avoided by careful preoperative planning of reconstruction.

Excision of Floor-of-Mouth Lesions

OPERATIVE PLANNING

Planning for excision of a lesion from the floor of the mouth is essentially the same as that for anterior glossectomy [see Anterior Glossectomy, Operative Planning, *above*]. If either or both of Wharton ducts are to be transected without excision of the submandibular glands, consideration must be given to the management of these glands.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

The surgical approach is the same as that described for glossectomy [see Anterior Glossectomy, Operative Technique, Step 1, *above*].

Step 2: Resection

The area to be excised, including adequate margins, is marked. The lesion is then excised with a monopolar electrocautery; as in a glossectomy, the cutting current is used to cut the mucosa and the coagulation current to cut the deeper tissues. Palpation is important for obtaining adequate deep surgical margins.

If the excision cuts across the Wharton duct, the duct should be identified and transected obliquely to create a wider opening. The transected stump is held with a 4-0 chromic catgut suture. Once the resection is complete, the duct is transposed posteriorly to the cut edge of the mucosa of the floor of the mouth and sutured in place with two or three 4-0 chromic sutures. During subsequent reconstruction, care should be taken not to obstruct the orifice of the duct.

Step 3: Reconstruction

After clean surgical margins have been verified by frozen-section examination, repair of the surgical defect is initiated. Small superficial defects of the floor of the mouth may be allowed to heal by secondary intention.

For small defects that do not connect to the neck, reconstruction with a 0.014 to 0.016 inch-thick split-thickness skin graft is appropriate. The graft is cut to size and sutured in place with 4-0 chromic sutures. Several perforations should be made in the graft to allow the egress of blood and serum. A Xeroform gauze bolster is fashioned to fit over the skin graft and sutured in place with 2-0 silk tie-over bolster stitches; alternatively, it may be held in place by a prefabricated dental prosthesis.

For larger defects, particularly those involving the tongue, a flap reconstruction typically yields the best functional results. In select cases, a platysma flap may be used for reconstruction of defects in the floor of the mouth. Other regional flaps tend to be bulky and difficult to shape to the contours of the defect. Free tissue transfer frequently provides the most suitable reconstructive tissue characteristics and the most favorable postoperative results. A free fasciocutaneous radial forearm flap is usually the optimal choice for reconstruction of floor-of-mouth defects when a flap is required.

TROUBLESHOOTING

Special care should be taken to identify the lingual nerve and artery so that these structures are not inadvertently divided. Meticulous hemostasis should be obtained in all cases. Any skin grafts used should be adequately sized and should not “tent up.” Generally, skin grafting and bolsters do not work well on mobile structures. Quilting grafts to the underlying tissues with multiple absorbable sutures can eliminate the need for a bolster and result in acceptable graft take.

POSTOPERATIVE CARE

Postoperative care of patients undergoing excision of floor-of-mouth lesions is virtually identical to that of patients undergoing anterior glossectomy [see Anterior Glossectomy, Postoperative Care, *above*].

COMPLICATIONS

Excision of floor-of-mouth lesions is associated with the same complications as anterior glossectomy [see Anterior Glossectomy, Complications, *above*].

Excision of Superficial or Plunging Ranulas

OPERATIVE PLANNING

Planning for excision of a superficial or plunging ranula resembles that for glossectomy. A Ring-Adair-Elwyn (RAE) tube is inserted orally and taped to the contralateral cheek. Cervical exploration is usually unnecessary because the cervical component of the ranula resolves after removal of the ipsilateral sublingual gland. In select cases, especially those involving disease recurrence after a previous attempt at excision, a transcervical approach should be considered.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

Ranulas are resected via the transoral approach. A bite block or a Molt retractor is used to gain exposure.

Step 2: Resection

A local anesthetic preparation with epinephrine is infiltrated into the area of the mucosal incisions. A small superficial ranula may be marsupialized and packed with gauze. The ranula is widely unroofed and the contents removed with suction. The margins of the cyst are sutured to the mucosa with 4-0 chromic sutures, and the cavity is packed with iodoform strip gauze. The gauze may be removed in 5 to 7 days.

A plunging ranula is treated with complete surgical excision of the cyst and the sublingual gland [see Figure 4]. A mucosal incision is made directly over the cyst. Careful dissection is carried out around the cyst and the associated gland. Hemostasis is achieved with a bipolar electrocautery, with care taken not to injure the adjacent lingual nerve. The submandibular gland duct is cannulated with a lacrimal probe to help guard against inadvertent injury to this structure. The incision is closed with 4-0 chromic suture.

TROUBLESHOOTING

Efforts should be made to identify the lingual nerve and artery to prevent inadvertent division of these structures.

Figure 4 Excision of plunging ranula. A mucosal incision is made over the cyst, dissection is done around the cyst and the associated sublingual gland, and the cyst and gland are completely excised.

Meticulous hemostasis should be obtained in all cases. If the submandibular gland duct is injured, it should be transected and the cut end sutured to the adjacent floor-of-mouth mucosa (sialodochoplasty).

COMPLICATIONS

The three main complications of the procedure for excising a ranula are among those that are also associated with anterior glossectomy and excision of floor-of-mouth lesions: injury to the lingual nerve, injury to the submandibular gland duct, and injury to the hypoglossal nerve [see Anterior Glossectomy, Complications, above].

Removal of Submandibular Gland Duct Stones

OPERATIVE PLANNING

When a submandibular gland duct stone is readily palpable in the floor of the mouth, a transoral approach is appropriate. When the stone is within the hilum of the gland, however, it generally cannot be removed transorally and often must be treated by excising the submandibular gland.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

The procedure is easily accomplished with local anesthesia in a cooperative patient. The patient is seated upright in the examining chair, and a topical anesthetic is applied to the oral cavity.

Step 2: Resection

A local anesthetic preparation with epinephrine is infiltrated into the floor of the mouth and around the duct in which the stone is palpated. A 2-0 silk suture may be placed around the duct behind the stone to prevent it from migrating back into the hilum of the gland.

A lacrimal probe is inserted into the duct and advanced to the stone in a retrograde manner. A mucosal incision is then made directly over the stone and extended downward to the duct, with the stone and the lacrimal probe serving as guides. The duct is incised and the stone delivered. As a rule, repair of the duct is not required.

TROUBLESHOOTING

Careful dissection directly onto the duct and stone usually serves to prevent inadvertent injury to the lingual nerve.

COMPLICATIONS

The main complications of the procedure are as follows:

1. Injury to the lingual nerve, resulting in numbness and loss of the sense of taste to the ipsilateral tongue
2. Stricture of the submandibular gland duct. This is an unusual complication that can be corrected by transecting the duct posterior to the stricture and suturing it to the mucosa of the floor of the mouth.

Resection of Hard Palate

OPERATIVE PLANNING

Careful evaluation is required to determine whether resection of part of the hard palate will suffice or whether a more

extensive dissection (e.g., maxillectomy) will be required. If it is anticipated that a dental prosthesis will be required, a dental consultation should be obtained before operation. When the lesion to be resected is superficial or only a limited amount of the bony hard palate must be resected, the procedure may be performed via the transoral approach.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

The patient is supine, with the bed turned 180° to facilitate the surgeons' access to the operative site. An oral RAE tube is inserted and taped in the midline. The lesion is approached transorally, and a Dingman or Crowe-Davis retractor is used to obtain exposure.

Step 2: Resection

An incision is made around the periphery of the lesion in such a way to maintain adequate margins; a monopolar electrocautery with a needle tip is ideal for this purpose. The periosteum is elevated away from the underlying bone, and the lesion is removed [see Figure 5].

When bone must be resected, the periosteum is elevated away from the incision site. A high-speed oscillating saw or an osteotome is used to make the cuts in the bone, after which the specimen is rocked free and removed.

Figure 5 Resection of hard palate. An incision is made around the lesion, with adequate margins maintained, the periosteum is lifted off the bone, and the lesion is removed.

Step 3: Reconstruction

After surgical margins have been verified by frozen-section review, repair of the surgical defect is initiated. Small mucosal defects may be allowed to heal by secondary intention. Small through-and-through resections may be closed by placing relaxing incisions laterally and advancing the mucosa to permit primary closure. Larger defects may be closed with palatal mucosal flaps. Many through-and-through defects can be closed quite satisfactorily with a dental obturator.

POSTOPERATIVE CARE

The patient should be maintained on a soft diet postoperatively. Meticulous oral hygiene is important. Oral rinses and flushes with normal saline or half-strength hydrogen peroxide should be performed at least four times daily and after meals.

COMPLICATIONS

The most significant potential complication of hard palate resection is oral antral or oronasal fistula; careful tissue reconstruction and the use of an obturator can prevent this complication.

Maxillectomy

OPERATIVE PLANNING

General anesthesia with muscle relaxation is essential for all types of maxillectomy. Either orotracheal or nasotracheal intubation may be appropriate, depending on the surgical approach. Skin incisions should be marked before the endotracheal tube is taped in place to avoid distortion of facial structures and skin lines. The patient should be supine in a 20° reverse Trendelenburg position. The eyes should be protected carefully (e.g., with a corneal shield or a temporary nylon tarsorrhaphy suture).

Radiographic evaluation plays a vital role in planning the surgical approach and determining the extent of resection required [see Figure 6]. Lesions of the infrastructure of the maxilla can be excised by means of partial maxillectomy via the transoral route. More extensive lesions usually must be accessed via facial incisions in conjunction with the transoral approach.

In all cases, a dental consultation should be obtained preoperatively so that a dental impression can be taken and an obturator fashioned for intraoperative use. Antibiotics should be given perioperatively and continued until nasal packing is removed.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

In addition to the transoral approach, maxillectomy usually requires exposure of the anterior face of the maxilla. There are several options for achieving such exposure, including a Weber-Ferguson incision and midface degloving. Midface degloving has the advantage of eliminating the need for visible facial incisions but yields limited exposure in the ethmoid region. The choice of surgical approach is determined by the extent of the planned resection and by the preferences of the patient and the surgeon.

Figure 6 Maxillectomy. Radiographic assessment helps determine the required extent of resection. Depicted are (a) medial maxillectomy, (b) subtotal maxillectomy without orbital exenteration, and (c) total maxillectomy with orbital exenteration.

In the Weber-Ferguson approach, the first step is to mark the path of the incision, which begins in the midline of the upper lip; extends through the philtrum; curves around the nasal vestibule and the ala; continues upward along the lateral nasal wall, just medial to the junction of the nasal sidewall and the cheek; and ends near the medial canthus. For added exposure in the ethmoid region, a Lynch extension, in which the incision is continued superiorly up to the medial eyebrow, may be performed. Alternatively, the Weber-Ferguson incision may be continued laterally in the subciliary crease along the inferior eyelid to the lateral canthus of the eye; this extension yields added exposure of the posterolateral aspect of the maxilla.

The skin incisions should initially be made with a scalpel and then continued with an electrocautery. The upper lip is divided through its full thickness, and the incision is continued in the gingivolabial sulcus laterally until the posterolateral aspect of the sinus is exposed. When possible, the infraorbital nerve is identified and preserved. The soft tissues

are elevated from the anterior wall of the maxillary sinus; if access to the pterygomaxillary fissure is desired, elevation should be continued up to the zygoma.

In a midface degloving, the skin of the lower face and nose is mobilized and retracted superiorly. A standard transfixion incision is made, transecting the membranous septum. Intercartilaginous incisions are then made bilaterally and connected to the transfixion incision. The incision is then continued laterally along the cephalic border of the lower lateral cartilage and across the floor of the nose. To prevent stenosis, a small Z-plasty or triangle is incised medially just before the transfixion incision is joined. The soft tissues are elevated over the nasal dorsum and the nasal tip with Joseph scissors. An incision is made in the gingivolabial sulcus with the monopolar cautery, and this incision is connected to the floor-of-nose incisions by means of gentle dissection. The soft tissues are then elevated from the anterior maxilla as far as the infraorbital rims and laterally as far as the zygoma.

Step 2: Resection

A Molt retractor is placed on the side opposite the side of the planned excision and opened as wide as possible to expose the hard palate and the alveolus.

The infraorbital rim should be preserved if it is possible to do so safely. Often a thin strip of the rim can be preserved even when the rest of the bone must be resected. If the orbital floor must be resected but the orbital contents can be preserved, the periorbital can be dissected away from the bone of the orbital floor and preserved. If the orbital contents are involved, an orbital exenteration must be performed in conjunction with the maxillectomy.

The cut along the infraorbital rim and superior anterior maxillary wall is made with a high-speed oscillating saw with a fine blade. The level at which this superior cut is made is determined by the extent of the resection. Lesions that are confined to the alveolus or the palate and do not invade the maxilla typically can be removed by excising the infrastructure of the maxilla. The line of transection is continued through the nasal process of the maxilla medially and downward through the piriform aperture. Laterally, the cut extends to the zygomatic process of the maxilla and around the posterolateral aspect of the sinus.

If the pterygoid plates are to be preserved, they are cut free by placing a curved osteotome along the posterior wall of the sinus and sharply dividing the plates from the sinus wall. If the pterygoid plates, part of the pterygoid musculature, or both are to be resected, the soft tissue attachments are cut sharply with curved Mayo scissors once the entire maxillary specimen has been mobilized.

The line of transection in the maxillary alveolus can run between two teeth if a suitable gap is evident. In the majority of cases, however, it is advisable to extract a tooth and make the cut through the extraction site. A power saw is used, and the cut is connected to the transection line through the nasal process of the maxilla and the piriform aperture. The hard palate mucosa is then incised lateral to the proposed cut in the hard palate bone to preserve a flap of mucosa that can be used to cover the raw cut bony edge of the palate. This incision is made with a needle-tip electrocautery and carried down to the bone of the hard palate. It should extend from the maxillary tuberosity posteriorly to the cut bone in the maxillary alveolus anteriorly, with care taken to obtain adequate mucosal margins. The mucosa is elevated for a short distance over the hard palate bone to create a short mucosal flap that is wrapped over the cut bony edge of the palate. The mucosal cut is connected around the maxillary tuberosity to the gingivolabial sulcus incision that was made earlier.

The hard palate is then cut with a power saw. Once all the bone cuts are complete, an osteotome may be used to connect them if necessary. The remaining soft tissue attachments are divided along the posterior hard palate with curved Mayo scissors. The surgical defect is packed to control bleeding. Bleeding from the internal maxillary artery is controlled by ligatures or ligating clips.

Step 3: Reconstruction

All sharp spicules of bone are débrided. The flap of hard palate mucosa is brought up over the cut bony edge of the palate and held in place with several Vicryl sutures. The anterior and posterior cut edges of the soft palate are reapproximated with absorbable sutures.

A split-thickness skin graft, 0.014 to 0.016 inches thick, is harvested and used to line the raw undersurface of the cheek flap. The skin graft is sutured to the mucosal edge of the cheek flap with 3-0 chromic sutures. Superiorly, the graft is not sutured but draped into position and retained by a layer of Xeroform packing and strip gauze coated with antibiotic ointment. Gentle pressure is applied to the packing so that it conforms to the defect. The previously fabricated dental obturator is placed to support the packing and to close the oral cavity from the nasal cavity. In a dentulous patient, the obturator may be wired to the remaining teeth; in an edentulous patient, it may be temporarily fixed in place with two screws placed in the remaining hard palate.

The skin incisions are closed in two layers, with interrupted absorbable sutures used for the deep layers and nonabsorbable monofilament sutures for the skin. If a lip-splitting incision was made, care must be taken to ensure exact reapproximation of the orbicularis oris and the vermilion border.

If the infraorbital rim was resected, it should be reconstructed to yield good aesthetic results. A split calvarial bone graft may be used for this purpose when there is adequate soft tissue coverage for the bone grafts available. When soft tissue coverage is inadequate or the orbital floor must be reconstructed, an osteocutaneous radial forearm or scapular flap may be employed, with excellent results.

Alternative Procedure: Peroral Partial Maxillectomy

The oral cavity is exposed with cheek retractors. An incision is made in the gingivobuccal sulcus and the mucosa of the hard palate, with care taken to maintain adequate margins; a monopolar electrocautery, set to use the cutting current, is suitable for this purpose. Incisions are made circumferentially through all the soft tissues up to the anterior wall of the maxilla and the hard palate. The infraorbital nerve should be preserved if it is not involved with the disease process.

The cut in the hard palate mucosa should be made lateral to the planned cuts in the hard palate bone to create a mucosal flap, which will be used to cover the cut bony edge of the hard palate. If necessary, teeth may be extracted to allow the surgeon to make bone cuts through tooth sockets while preserving adjacent teeth. The bone is cut with a high-speed power saw, and an osteotome is used to divide any remaining bony attachments and deliver the specimen. If the mucosa remaining in the maxillary antrum is not diseased, it need not be removed.

A split-thickness skin graft, 0.014 to 0.016 inches thick, is harvested from the anterolateral thigh and used to reline the raw buccal mucosa area. The graft is sutured to the cut edge of the buccal mucosa with 4-0 chromic catgut. Xeroform and strip gauze coated with antibiotic ointment are gently packed into the defect to secure the skin graft. The previously fabricated dental obturator is wired to the remaining teeth to hold the packing in place.

TROUBLESHOOTING

If a lip-splitting incision is planned, lip contraction can be reduced and vermilion border realignment improved by employing a stair-step lip incision and a Z-plasty. A single intraoperative steroid dose reduces facial edema without compromising wound healing. Retention of the obturator is

aided by the band of scar tissue that forms at the junction of the mucosa and the skin graft. Covering the cut edge of the hard palate bone with mucosa eliminates pain caused by pressure from the obturator on thinly covered bone.

If more than a small area of the floor of the orbit is resected, it should be repaired to prevent enophthalmos. Epiphoria is uncommon; when it occurs, it is related to scarring of the nasolacrimal duct. Identifying the duct and transecting it obliquely should reduce the incidence of this complication.

POSTOPERATIVE CARE

A nasogastric tube is placed at the end of the procedure. Many patients are able to begin a liquid diet and advance to a soft diet within a few days after operation. A soft diet should be continued for at least 2 weeks. Oral rinses and flushes with normal saline or half-strength hydrogen peroxide should be performed at least four times daily and after meals.

The obturator and the packing may be removed from the cavity in 7 to 10 days. The obturator should be replaced to maintain oral competence. The prosthodontist makes a final obturator once healing is complete and the cavity has stabilized. Facial incisions are cleaned twice daily and coated with antibiotic ointment. Facial sutures are removed 5 to 7 days after operation.

COMPLICATIONS

The main complications of maxillectomy are as follows:

1. Enophthalmos and hypophthalmos, which create a cosmetic deformity
2. Infraorbital nerve injury, which results in anesthesia or paresthesia of the ipsilateral cheek and upper lip. On occasion, the infraorbital nerve may have to be sacrificed as part of the planned resection.
3. Epiphoria, caused by scarring of the nasolacrimal duct
4. Difficult retention of the dental prosthesis, which can usually be prevented by careful preoperative evaluation and appropriate choice of reconstructive method. In select cases, free tissue reconstruction without a dental prosthesis may be optimal.

Mandibulectomy

OPERATIVE PLANNING

General anesthesia with muscle relaxation is essential for all types of mandibulectomy. Either orotracheal or nasotracheal intubation is appropriate, depending on the surgical approach and the extent of the planned resection. A tracheostomy should be performed whenever significant postoperative swelling or airway compromise is anticipated. Skin incisions should be marked before the endotracheal tube is taped in place.

Preoperative radiographic evaluation is essential for planning the surgical approach and determining the extent of the proposed resection. For lesions without radiographic or clinical evidence of bone invasion, a marginal mandibulectomy is often appropriate. This procedure may also be performed to obtain adequate surgical margins for lesions that are in close proximity to the mandible. When the lesion is small, it is occasionally possible to perform marginal mandibulectomy via the transoral route. For more extensive lesions and those that show evidence of bone invasion, a segmental mandibulectomy is required.

The patient should be supine in a 20° reverse Trendelenburg position. Perioperative antibiotics should be administered.

OPERATIVE TECHNIQUE

Step 1: Exposure

Wide exposure for access to primary tumors of the oral cavity and the mandible may be achieved by means of either a lower-cheek flap or a visor flap. The former is often preferable in that it allows resection of the primary and ipsilateral lymph nodes.

To create a lower-cheek flap, a lip-splitting incision is made through the full thickness of the lower lip and carried down through the chin tissues to the periosteum of the anterior mandible [see Figure 7]. This incision may be made straight through the mental subunit with a Z-plasty placed at the mental crease; alternatively, it may be made around the mental subunit. The incision is continued vertically to approximately the level of the thyrohyoid membrane and then extended laterally to the mastoid along a skin crease. The transverse component of the incision should be made at least two fingerbreadths below the mandible to prevent injury to the marginal mandibular nerve. The cheek flap is fully developed by incising the oral mucosa along the gingivolabial sulcus while maintaining adequate surgical margins around the lesion. The periosteum of the mandible is then elevated and the cheek flap retracted to expose the mandible.

A visor flap [see Figure 3] has the advantage of not requiring a lip-splitting incision and provides adequate exposure for lesions of the anterior oral cavity. However, it is inadequate for exposing lesions posterior to the middle third of the tongue or in the area of the retromolar trigone and may lead to anesthesia of the lower lip as a consequence of the need to divide both mental nerves. The technical aspects of

Figure 7 Mandibulectomy. A cheek flap is created by making a lip-splitting incision and extending it down to the level of the thyrohyoid membrane and then laterally to the mastoid along a skin crease.

visor flap creation are summarized elsewhere [see Anterior Glossectomy, Operative Technique, Step 1, *above*].

Step 2: Resection

If a plate is to be used in the reconstruction of the mandible, a template and a reconstruction plate are shaped and conformed to the mandible before resection. The segment of mandible to be resected is marked. The plate is applied to the buccal cortex of the mandible, and screw holes are predrilled in the mandible for gauging of depth. The plate is then set aside until needed for reconstruction.

Mucosal incisions are made around the lesion with the electrocautery, with care taken to maintain adequate surgical margins. The mandibular segment to be removed is cut with a high-speed sagittal saw. The lingual nerve and the hypoglossal nerve are preserved if possible. Muscle attachments to the resected mandibular segment are sharply divided, allowing the surgical specimen to be delivered [see Figure 8].

In some cases, only a marginal mandibulectomy of the lingual or alveolar cortex of the mandible is necessary. The

bone is cut with a high-speed saw in such a way that the cuts are rounded off and lack sharp angles, which are prone to fracturing. Once the bone cuts are made, an osteotome may be used to free the specimen.

Step 3: Reconstruction

When a marginal mandibulectomy has been performed, a plate is sometimes needed to support the mandible. This is especially likely to be the case for a patient with a thin edentulous mandible, in which the remaining bone cannot withstand the forces of mastication.

When the anterior mandible has been resected, it must be reconstructed with vascularized bone. Any of several free flaps may be employed, depending on the tissue requirements for the planned reconstruction. Free tissue flaps from the fibula, the scapula, or the iliac crest can provide bone that is suitable for mandibular reconstruction, as well as soft tissue that is suitable for reconstruction of accompanying mucosal and cutaneous defects.

After lateral mandibular resections, good results can be achieved by using mandibular reconstruction plates with suitable soft tissue reconstruction. There is a significant risk of plate failure, however, especially in dentulous patients. In many cases, replacing the resected portion of the mandible with vascularized bone—especially if the defect is longer than a few centimeters—yields better long-term results than using a reconstruction plate alone.

POSTOPERATIVE CARE

A nasogastric tube is placed at the end of the surgical procedure; most patients will need to be fed through this tube until their incisions are healed. A soft diet should be continued for 6 weeks. Oral rinses and flushes with normal saline or half-strength hydrogen peroxide should be performed at least four times a day and after meals.

Facial incisions are cleaned twice a day and coated with antibiotic ointment. Facial sutures are removed 5 to 7 days after operation.

TROUBLESHOOTING

Contouring the reconstruction plate to the mandible before resecting the mandibular segment will prevent malocclusion and enhance cosmetic results. Preserving the lingual nerve and the hypoglossal nerve, when possible, will improve postoperative swallowing and speech. The marginal mandibular nerve should be identified and protected as well. If a lip-splitting incision is used, performing a stair-step lip incision and a Z-plasty reduces lip contraction and improves vermilion border realignment.

COMPLICATIONS

The main complications of mandibulectomy are as follows:

1. Malocclusion, caused by inaccurate repair of the resected mandibular segment
2. Plate failure or fracture, which can be reduced by reconstructing bony defects larger than 1 to 2 cm with revascularized bone
3. Oral incompetence, caused by inadequate reconstruction of anterior mandibular defects.

Financial Disclosures: None Reported

Figure 8 Mandibulectomy. The segment to be removed is cut with a high-speed saw, with care taken to preserve the lingual and hypoglossal nerves if possible, and the muscle attachments to the segment are sharply divided to free the surgical specimen.

6 PAROTIDECTOMY

Leonard R. Henry, MD, and John A. Ridge, MD, PhD, FACS

Anatomic Considerations

The parotid (“near the ear”) gland, the largest of the salivary glands, occupies the space immediately anterior to the ear, overlying the angle of the mandible. It drains into the oral cavity via Stensen’s duct, which enters the oral vestibule opposite the upper molars. The gland is invested by a strong fascia and is bounded superiorly by the zygomatic arch, anteriorly by the masseter muscle, posteriorly by the external auditory canal and the mastoid process, and inferiorly by the sternocleidomastoid muscle. The masseter muscle, the styloid muscles, the posterior belly of the digastric muscle, and a portion of the sternocleidomastoid muscle lie deep to the parotid. Terminal branches of the external carotid artery, the facial vein, and the facial nerve are found within the gland. Parasympathetic innervation to the parotid is via the otic ganglion, which gives fibers to the auriculotemporal branch of the trigeminal nerve. Sympathetic innervation to the gland originates in the sympathetic ganglia and reaches the auriculotemporal nerve by way of the plexus around the middle meningeal artery.¹

The facial nerve trunk exits the stylomastoid foramen and courses toward the parotid. Once inside the gland, it commonly bifurcates into superior (temporal-frontal) and inferior (cervicomarginal) divisions before giving rise to its terminal branches. The nerve branching within the parotid can be quite complex, but the common patterns are well known and their relative frequencies well established.^{2,3} The portion of the parotid gland lateral to the facial nerve (about 80% of the gland) is designated as the superficial lobe; the portion medial to the facial nerve (the remaining 20%) is designated as the deep lobe. Deep-lobe tumors often present clinically as retro-mandibular or parapharyngeal masses, with displacement of the tonsil or the soft palate appreciated in the throat.

Operative Planning

Obtaining informed consent for parotidectomy entails discussing both the features and the potential complications of the procedure. It is appropriate to address the possibility of facial nerve injury, but in doing so, the surgeon should not neglect other, far more common sequelae, such as cosmetic deformity, earlobe numbness, and Frey syndrome. Even conditions that are expected beforehand may prove distressing or debilitating for the patient. The risk of complications such as nerve injury is greater in cases involving reoperation or resection of malignant or deep-lobe tumors. The overwhelming majority of parotid tumors, however, are benign and lateral to the facial nerve. Accordingly, in what follows, we focus primarily on superficial parotidectomy, referring to variants of the procedure where relevant.

Excellent lighting, correctly applied traction and countertraction, adequate exposure, and clear definition of

the surgical anatomy are essential in parotid surgery. The use of magnifying loupes and headlights is recommended. General anesthesia without muscle relaxation should be employed.

The patient is placed in the supine position, with the head elevated and turned away from the side undergoing operation and with the neck slightly extended. The table is positioned to allow the first assistant to stand directly above the patient’s head, while the surgeon faces the operative field. A small cottonoid sponge is placed in the external auditory canal, where it remains for the duration of the procedure to prevent otitis externa from blood clots in the external auditory canal. The skin is painted with an antiseptic agent. A single perioperative dose of an antibiotic is administered.

The patient is draped in a fashion that permits the operating team to see all of the muscle groups innervated by the facial nerve. To this end, we employ a head drape that incorporates the endotracheal tube and hose. This drape secures the airway, keeps the tube from interfering with the surgeon, and permits rotation of the head without tension on the endotracheal tube. The skin of the upper chest and neck is widely painted and draped with a split sheet to allow additional exposure in the unlikely event that a neck dissection or a tracheostomy becomes necessary. The nose, the lips, and the eyes are covered with a sterile transparent drape that allows observation of movement during the procedure and permits access to the oral cavity (if desired) [see *Figure 1*].

Operative Technique

STEP 1: INCISION AND SKIN FLAPS

The incision is planned so as to permit excellent exposure with good cosmetic results. It begins immediately anterior to the ear, continues downward past the tragus, curves back under the ear (staying close to the earlobe), and finally turns downward to descend along the sternocleidomastoid muscle [see *Figure 1*]. Either all or part of this incision may be used, depending on circumstances. The incision is marked before draping. Skin creases typically help conceal the resulting scar.

Skin flaps are then created to expose the parotid gland. A tacking suture is placed within the dermis of the earlobe so that it can be retracted posteriorly. Skin hooks are used to apply vertical traction. The anterior flap is created superficial to the parotid fascia to afford access to the appropriate dissection plane. Vertically oriented blunt dissection minimizes the risk of injury to the distal branches of the facial nerve [see *Figure 2*]. The face is observed for muscle motion. The flap is raised until the anterior border of the gland is identified. The facial nerve branches are rarely encountered during flap elevation until they emerge from the parenchyma of the

Figure 1 Parotidectomy. (a) Shown are the recommended head position and incision. A transparent drape is placed over the eyes, the lip and oral cavity. (b) The head drape incorporates the hose from the endotracheal tube.

parotid. If muscle movement occurs, the flap has been more than adequately developed. The anterior flap is retracted with a suture through the dermis.

The posterior-inferior skin flap is then elevated in a similar manner. Careful dissection is performed to define the relationship of the parotid tail to the anterior border of the sternocleidomastoid. During this portion of the procedure, the great auricular nerve is identified coursing cephalad and superficial to the sternocleidomastoid muscle. Uninvolved

branches of this nerve should be preserved if possible to prevent postoperative numbness of the earlobe.^{4,5} The parotid tail is dissected away from the sternocleidomastoid muscle. Vertical traction is applied to the gland surface with clamps to facilitate exposure.

Troubleshooting

A favorable skin crease, if available, may be used for the incision to improve the postoperative cosmetic result;

Figure 2 Parotidectomy. (a) Shown is the creation of the anterior skin flap superficial to the parotid gland. (b) Vertically oriented blunt dissection minimizes the risk of injury to facial nerve branches as they exit the gland.

however, it is important to keep the incision a few millimeters from the earlobe itself. A wound at the junction of the earlobe with the facial skin will distort the earlobe and create a visible contour change. An incision behind the tragus may lead to similar problems.

STEP 2: IDENTIFICATION OF FACIAL NERVE

Once the skin flaps have been developed and retracted, the next step is to identify the facial nerve. Usually, the nerve may be identified either at its main trunk (the antegrade approach) or at one of the distal branches, with subsequent dissection back toward the main trunk (the retrograde approach). For a lateral parotidectomy, our preference is to identify the main trunk first (unless it is thoroughly obscured by tumor or scar).

Antegrade Approach

The dissection plane is immediately anterior to the cartilage of the external auditory canal. The gland is mobilized anteriorly by means of blunt dissection. To reduce the risk of a traction injury, tissue is spread in a direction that is perpendicular to the incision and thus parallel to the direction of the main trunk of the nerve [see Figure 3]. The nerve trunk can usually be located underlying a point about halfway between the tip of the mastoid process and the ear canal. In addition, there are several anatomic landmarks that facilitate identification of the nerve, including the tragal pointer, the posterior belly of the digastric muscle, and the tympanomastoid suture. Of these, the tympanomastoid suture is closest to the main trunk of the facial nerve.⁶ The clinical utility of this landmark is limited, however, because the tympanomastoid suture is not easily appreciated in every case. In addition,

Figure 3 Parotidectomy. Depicted is identification of the facial nerve at its trunk. A wide trough is created anterior to the external auditory canal and deepened by spreading a blunt curved instrument in a direction perpendicular to the incision and parallel to the nerve trunk. Anatomic landmarks assist in identification of the nerve.

deep-lobe tumors may displace the nerve from its normal location. For appropriate and safe exposure of the nerve trunk, it is necessary to mobilize several centimeters of the parotid, thereby creating a trough rather than a deep hole. Small arteries run superficial and parallel to the facial nerve; these must be divided. Use of the electrocautery this close to the nerve is potentially hazardous. Bleeding is typically minor but nonetheless must be controlled.

Retrograde Approach

As noted, when the main trunk cannot be exposed, the most common alternative method of identifying the facial nerve is to find a peripheral branch and then dissect proximally toward the main trunk. Which branch is sought may depend on factors such as the surgeon's comfort with the anatomy and the known consistency of the nerve branch's location. In this setting, tumor bulk is often the deciding factor.

The anatomic relationships between the nerve branches and various landmarks can be exploited for more efficient identification. For example, the marginal mandibular branch of the facial nerve characteristically lies below the horizontal ramus of the mandible.⁷ Often, the facial vein can be traced toward the parotid on the submandibular gland; the nerve branch can then be found coursing perpendicular and superficial to the vein. The buccal branch of the facial nerve has a typical location in the so-called buccal pocket—the area inferior to the zygoma and deep to the superficial musculoaponeurotic layer, which contains the buccal fat pad and Stensen's duct in addition to the buccal branch.⁷ The zygomatic branch of the facial nerve lies roughly 3 cm anterior to the tragus, and the temporal-frontal branch lies at the midpoint between the outer canthus of the eye and the junction of the ear's helix with the preauricular skin.⁷ Nerve branches to the eye should be dissected with particular care: even transient weakness of these branches may have a significant impact on morbidity.

Troubleshooting

Special efforts should be made to ensure that the cartilage of the ear canal is not injured during exposure of the facial nerve trunk. Any injury to this cartilage must be repaired, or else an intense whistling will be heard from the closed suction drain after operation.

The anxiety associated within isolation of the nerve trunk may be alleviated somewhat by keeping in mind that the nerve typically lies deeper than one might expect. In a study of 46 cadaver dissections, the facial nerve was found to lie at a median depth of 22.4 mm from the skin at the stylomastoid foramen (range, 16 to 27 mm). The diameter of the nerve trunk was found to range from 1.1 to 3.4 mm.⁸ In our experience, the facial nerve trunk is slightly larger than the nearby deep vessels.

Some surgeons advocate the use of a nerve stimulator to aid in identifying the facial nerve trunk or its branches; however, we have substantial reservations about whether this measure should be employed on a regular basis [see Complications, Facial Nerve Palsy, below]. Knowledge of the anatomy and sound surgical technique are the keys to a safe parotidectomy; it may be hazardous to rely too much on practices that may diminish them.

STEP 3: PARENCHYMAL DISSECTION

Once identified, the plane of the facial nerve remains uniform throughout the gland (unless the nerve is displaced by a tumor) and serves to guide the parenchymal dissection. Although some surgeons advocate the use of hemostatic devices for parenchymal division,^{9,10} our practice is to divide the substance of the parotid gland sharply and use ligatures as appropriate when bleeding is encountered. Usually, there is no significant hemorrhage: loss of more than 30 mL of blood is rare.

The parenchymal dissection proceeds directly over the facial nerve. We favor using fine curved clamps for this portion of the procedure. To prevent trauma to the nerve, care must be taken to resist the tendency to rest the blades of the clamp on the nerve during dissection. Each division of the gland should reveal more of the facial nerve [see Figure 4]. When this is the case, the surgeon can continue the parenchymal dissection with confidence that the nerve will not be injured. As a rule, if a parenchymal division does not immediately show more of the facial nerve, it is in an improper plane.

We do not regularly resect the entire lateral lobe of the parotid unless the tumor is large and such resection is required on oncologic grounds. The goal in resecting the substance of the parotid is to obtain sound margins while preserving the remainder of the gland. This so-called partial superficial parotidectomy has been shown to reduce the incidence of Frey syndrome without increasing the rate of recurrence of pleomorphic adenoma.¹¹ The plane of dissection is developed along facial nerve branches until the lateral margins have been secured. This is the portion of the procedure during which the risk of nerve injury is highest. Once the lateral margins have been secured, the parenchymal dissection can proceed from deep to superficial for the excision of the tumor.

Figure 4 Parotidectomy. Dissection of the gland parenchyma is carried out over the branches of the facial nerve to minimize the risk of nerve injury. Each division of the substance of the gland should reveal more of the facial nerve.

The vertical portion of the dissection seldom poses a threat to the integrity of the facial nerve, but care must be taken to maintain appropriate margins. If division of Stensen's duct is required, the distal remnant may be either left open¹² or ligated.

Caution is appropriate in the resection of deep-lobe tumors. Tumors medial to the facial nerve may displace this structure laterally. Thus, after establishing the plane of the facial nerve, the surgeon must remain careful when dissecting near the tumor to keep from injuring the nerve. Once the substance of the gland obscuring the tumor has been removed, the nerve branches in the area of the tumor are retracted to allow exposure of the deep portion of the gland and facilitate resection. Traction injury to the nerve may still result in transient facial weakness.

Troubleshooting

Complete superficial parotidectomy with full dissection of all facial nerve branches is seldom necessary, though in some cases it is mandated by tumor size or histologic findings. Removal of the entire superficial lobe with the intention of obtaining a larger lateral margin is rarely useful, because the closest margin is usually where the tumor is nearest the facial nerve. Even temporary paresis of the temporal-frontal branch of the facial nerve may have devastating consequences, and dissection near this branch is usually unnecessary in treating a benign tumor in the parotid tail. Any close margins remaining after nerve-preserving cancer treatment can be addressed by means of postoperative radiation therapy, usually with excellent results.¹³

The question of whether to sacrifice the facial nerve almost invariably arises in the setting of malignancy. In our view, this measure is seldom necessary. Benign tumors tend to displace the nerve, not invade it. Sacrifice of the nerve probably does not enhance survival.^{14,15} Although this issue remains a subject of debate, our practice, like that of others,¹⁶ is to sacrifice only those branches intimately involved with tumor. Repair, if feasible, should be performed [see Complications, Facial Nerve Injury, below].

STEP 4: DRAINAGE AND CLOSURE

Before closure, absolute hemostasis is confirmed (including hemostasis during the Valsalva maneuver, which is approximated by transiently increasing airway pressure to 30 cm H₂O¹). We may then assess the integrity of the facial nerve with a nerve stimulator. A 5 mm closed suction drain is placed through a stab incision posterior to the inferior aspect of the ear in a hair-bearing area. The tip of the drain is loosely tacked to the sternocleidomastoid muscle, with care taken to avoid direct contact with the facial nerve). The wound is closed with the drain placed on continuous suction. The skin is closed with interrupted 5-0 nylon sutures. Bacitracin is applied to the wound. No additional dressing is necessary or desirable [see Figure 5].

Troubleshooting

The use of interrupted skin sutures instead of a continuous suture allows the surgeon to perform directed suture removal to drain the rare postoperative hematoma or fluid collection instead of reopening the entire wound.

Figure 5 Parotidectomy. Shown is drainage and closure after parotidectomy. (a) A closed suction drain is placed in the operative bed and loosely tacked to the sternocleidomastoid muscle. (b) Interrupted monofilament sutures are used for the skin. Bacitracin is applied. No additional dressings are used.

Postoperative Care

Facial nerve function is evaluated in the recovery room, with particular attention paid to whether the patient is able to close the eyelid. The patient resumes eating when nausea (if any) abates. Pain is generally well controlled by means of oral agents. At discharge, the patient should be warned to protect the numb earlobe against cold injury. The closed suction drain is kept in place for 5 to 7 days (until the first postoperative visit) to minimize the risk of salivary fistula.

Complications

FACIAL NERVE INJURY

Studies have found that transient paralysis of all or part of the facial nerve occurs in 17 to 100% of patients undergoing parotidectomy,^{17–20} depending on the extent of the resection and the location of the tumor. Fortunately, permanent paralysis is uncommon, occurring in fewer than 5% of cases.^{19,21}

Nerve monitoring has been advocated to reduce the incidence or severity of facial nerve injury, particularly in the

setting of surgery for a recurrent parotid tumor.²² To date, however, no randomized trial has demonstrated that intraoperative facial nerve monitoring or nerve stimulators yield any significant reduction in the incidence of facial nerve paralysis after either primary parotidectomy or recurrence surgery. Indeed, indiscriminate use of nerve monitoring and nerve stimulators may imbue the surgeon with a false sense of security and cause him or her to pay insufficient attention to the appearance of nerve tissue. Transient nerve dysfunction may follow inappropriate (or even appropriate and unavoidable) trauma to or traction and pressure on nerve trunks. Nerve monitoring does not prevent such problems; moreover, it adds to the cost of the procedure and lengthens the operating time.²³ Some, in fact, have suggested that nerve stimulators may actually increase transient dysfunction. Accordingly, our use of nerve stimulators is selective.

The management of facial nerve injury depends on when the injury is discovered and on how sure the surgeon is of the anatomic integrity of the nerve. If the injury is discovered intraoperatively, it should be repaired if possible. Primary repair—performed with interrupted fine permanent monofilament sutures under magnification²⁴—is preferred if sufficient nerve is available for a tension-free anastomosis. If both transected nerve ends are identified but tension-free repair is not feasible, interposition nerve grafts may be used. A sensory nerve harvested from the neck (e.g., the great auricular nerve) is often employed for this purpose. If the nerve is injured (or deliberately sacrificed) in conjunction with treatment of malignancy, use of nerve grafts from distant sites may be indicated.²⁴

If unexpected facial nerve dysfunction is identified in the postanesthesia care unit and if the surgeon is unsure of the anatomic integrity of the nerve (ideally, a rare occurrence), the patient should be returned to the operating room for wound exploration so that either the continuity of the nerve can be confirmed or the injury to the nerve can be identified and, if possible, repaired. When the surgeon is certain that the nerve is intact, facial nerve dysfunction can be managed without reoperation, in anticipation of recovery²⁴; however, this may take many months.

Management of enduring facial nerve paralysis (from any cause) is beyond the scope of our discussion and constitutes a surgical subspecialty in itself.²⁴

GUSTATORY SWEATING (FREY SYNDROME)

Gustatory sweating, or Frey syndrome, occurs in most patients after parotidectomy; it has been seen after submandibular gland resection as well. The symptom complex includes sweating, skin warmth, and flushing after chewing food and is caused by cross-innervation of the parasympathetic and sympathetic fibers supplying the parotid gland and the overlying skin. The reported incidence of Frey syndrome varies greatly, apparently depending on the sensitivity of the test used to elicit it. When Minor's starch

iodine test is employed, the incidence of Frey syndrome may reach 95% at 1 year after operation.²⁵ Fortunately, the majority of patients have only subclinical findings, and only a small fraction complain of debilitating symptoms.²⁵ Most symptomatic patients are adequately treated with topical antiperspirants; eventually, however, they tend to become noncompliant with such measures, preferring simply to dab the face with a napkin while eating.²⁵ Despite the relatively low incidence of clinically significant Frey syndrome, there is an extensive literature addressing prevention and additional treatment of this condition.^{11,21,26–34}

SIALOCELE (SALIVARY FISTULA)

Sialocele, or salivary fistula, has been reported to occur after 1 to 15% of parotidectomies.^{11,35} Although this condition is generally minor and self-limited, it may nonetheless be embarrassing for the patient. We believe that the incidence of sialocele can be reduced by maintaining closed suction drainage for 5 to 7 days (to facilitate adhesion of the skin flaps to the underlying parotid parenchyma). Postparotidectomy salivary fistula is usually attributable to gland disruption rather than to duct transection and therefore tends to resolve without difficulty.³⁶ Compression dressings are generally effective.³⁵ Anticholinergic agents have been used in this setting as well.^{37–40} Low-dose radiation,⁴¹ completion parotidectomy, and tympanic neurectomy⁴² have all been employed in refractory cases.

COSMETIC CHANGES

Parotidectomy creates a hollow anterior and inferior to the ear, which may extend behind the mandible and may reach a significant size in patients with large or recurrent tumors. This cosmetic change is a necessary feature of the procedure, not a complication; nonetheless, it should be discussed with the patient before operation. Many augmentation methods, using a wide variety of techniques, have been devised for improving postoperative appearance (as well as alleviating Frey syndrome).^{27–31,43,44} All of these methods have limitations or drawbacks that have kept them from being widely applied and accepted.

Outcome Evaluation

With proper surgical technique, superficial or partial superficial parotidectomy can be performed safely and within a reasonable operating time. The requirement for blood transfusions should be vanishingly rare. Given adequate exposure, good knowledge of the relevant anatomy, limited trauma to the nerve, and appropriate use of closed suction drains (see above), complications should be uncommon. Although patients may tolerate parotidectomy on an outpatient basis, we prefer to keep them in the hospital overnight. Patients should be able to leave the hospital with minimal pain, comfortable with their drain care, by the morning of postoperative day 1.

Preoperative Evaluation

In the majority of cases, cancer in the neck is a metastasis from a primary lesion in the upper aerodigestive tract, although metastases from skin, thyroid, and salivary gland neoplasms are also encountered. Lymphomas often present as cervical lymphadenopathy.

When a patient presents with a suspicious lesion in the neck, a careful history and physical examination should be performed, along with a thorough evaluation of the aerodigestive tract aimed at locating the source of possible metastatic disease. Fine-needle aspiration (FNA) of the neck mass should then be done to determine whether the mass is malignant. FNA can often differentiate between epithelial and lymphoid malignancies, and this differentiation will guide subsequent workup. The reported sensitivity of FNA ranges from 92 to 98% and the reported specificity from 94 to 100%.^{1,2}

If FNA reveals the presence of atypical lymphoid cells, an excisional lymph node biopsy may be performed if additional tissue is required for adequate tumor typing. An excisional biopsy may also be performed if the FNA is negative or indeterminate, the surgeon suspects a malignancy, and the rest of the physical examination yields negative results. Routine excisional biopsy of neck masses for diagnostic purposes is not recommended, however, because it may result in tumor spillage into the wound and complicate subsequent definitive resection.

Once the presence of an epithelial malignancy is established, the primary site of the lesion must be determined. The clinical setting provides clues regarding the source of the cancer. For example, in an elderly patient with a previous history of skin cancer, with abnormal cutaneous lesions over the scalp or face and a nontender, enlarging posterior triangle neck mass, a metastasis from a cutaneous cancer is suspected. Alternatively, in a 50-year-old alcohol abuser with an enlarging level II lymph node also complaining of a several-month history of sore throat and otalgia, a metastasis from a pharyngeal primary cancer should be entertained. In any patient with metastatic cervical adenopathy thought to originate in the upper aerodigestive tract, panendoscopy and biopsy with general anesthesia are mandatory for locating and characterizing the primary source of the tumor and ruling out the presence of synchronous lesions. The most common occult primary sites are the base of the tongue, the tonsils, and the nasopharynx. Imaging studies (e.g., computed tomography [CT] and magnetic resonance imaging) may be helpful in locating the source of a cervical metastasis. Positron emission

tomography (PET) detects lesions with increased metabolic activity but has the limitation of being unable to detect lesions smaller than 1 cm in diameter. Primary lesions greater than 1 cm in diameter usually are easily identified on physical examination and other imaging studies; thus, PET scans add little in this setting. In 5 to 10% of patients who present with a metastatic node, the primary lesion is never found despite extensive workup.

INCIDENCE AND IMPACT OF NECK METASTASES

Cutaneous Squamous Cell Carcinoma

The incidence of cervical metastases is governed by many factors. Cervical metastases from cutaneous squamous cell carcinomas are rare, occurring in 2 to 10% of cases. However, certain lesions—those that are greater than 2 cm in diameter; are recurrent; are deeper than 6 mm; involve the ear, the temple, or the classic H zone; occur in an immunocompromised patient; or are poorly differentiated—have a significant occult metastatic rate, ranging from 20 to 60%. The presence of cervical metastases reduces 5-year survival to about 32%,³ which suggests that early intervention for high-risk cutaneous lesions, involving regional lymphadenectomy, sentinel lymph node (SLN) biopsy, or irradiation of at-risk lymph node basins, may be warranted.

Salivary Gland Neoplasms

With salivary gland neoplasms [see 2:1 Oral Cavity Lesions], the incidence of cervical metastases is related to the histopathology and the size of the tumor. The most aggressive salivary gland lesions are squamous cell carcinoma, carcinoma ex pleomorphic adenoma, adenocarcinoma, and salivary ductal carcinoma. Patients with these lesions often have cervical metastases at presentation that warrant a therapeutic neck dissection [see Table 1]. How best to manage occult cervical salivary gland metastatic disease is controversial. The occult metastatic rate for aggressive lesions ranges from 25 to 45%. For such lesions, a selective neck dissection is typically incorporated into the surgical approach.⁴

Metastatic Well-Differentiated Thyroid Cancer

Cervical lymph node metastases are present in 10 to 15% of patients with well-differentiated thyroid carcinoma. The impact of nodal metastases on local recurrence and survival has not been established. Other factors (e.g., age, sex, tumor extent, and distant metastases) appear to have a greater effect on prognosis. Nevertheless, in the presence of clinically

Table 1 Incidence of Cervical Metastases in Selected Head and Neck Cancers

Tumor	Incidence of Cervical Adenopathy (%)
Cutaneous squamous cell carcinoma	2–10
Salivary gland malignancies	30–70
Mucoepidermoid carcinoma (high grade)	
Adenoid cystic carcinoma	8
Malignant mixed tumor	25
Squamous cell carcinoma	46
Salivary duct carcinoma	50
Acinic cell carcinoma	40
Metastatic well-differentiated thyroid cancer	10–15
Squamous cell carcinoma of upper aerodigestive tract	
Alveolar ridge	30

Tongue base	78
Bilateral	20

apparent nodal disease, a formal neck dissection is advised: so-called cherry-picking operations or limited lymph node excisions result in higher rates of recurrence.⁵

Squamous Cell Carcinoma of the Upper Aerodigestive Tract

With upper aerodigestive tract squamous cell carcinomas, the incidence of cervical metastases is related to the site of the primary lesion, the size of the tumor, the degree of differentiation, the depth of invasion, and other biologic factors. A significant proportion of head and neck cancer patients who harbor clinically silent primary tumors of the base of the tongue, the tonsils, or the nasopharynx initially present with cervical adenopathy [see Table 1]. These sites lack anatomic barriers that limit tumor spread and are supplied by rich lymphatic networks that facilitate metastasis. In contrast, patients with glottic and lip cancers rarely present with clinical adenopathy.

The presence of cervical metastases negatively affects prognosis and has been associated with increased recurrence rates and reduced disease-free and overall survival. The presence of clinical adenopathy decreases survival by 50%. Metastatic tumors that rupture the lymph node capsule—a process known as extracapsular spread (ECS)—are biologically more aggressive. Patients who have palpable cervical lymphadenopathy with ECS manifest a 50% decrease in survival compared with those who have palpable cervical lymphadenopathy without ECS.⁶ In addition, about 50% of clinically negative, pathologically positive neck specimens exhibit ECS. Clinically negative, pathologically positive, and ECS-positive specimens are

associated with a high risk of regional recurrence and distant metastases.^{7–9} The presence of ECS in lymph node metastases may, in fact, be the single most important prognostic factor in patients with head and neck cancer. Identification of this patient subset may be the most important benefit of elective neck dissection in that it allows these patients to be offered adjuvant therapy. The presence of extracapsular extension is an indication for adjuvant concurrent chemoradiation, which has been shown to decrease the risk of recurrence and improve survival in randomized clinical trials.^{10,11}

Whereas anatomic and pathologic factors (e.g., ECS) have long been known to predict tumor behavior, it is only comparatively recently that the impact of comorbidity has been well characterized. When patients are stratified by tumor stage, those with comorbidities fare worse. In fact, the impact of comorbidity on overall survival is greater than that of tumor stage or treatment type.^{12,13} In addition, comorbidity is associated with both increased frequency and increased severity of surgical complications. These factors may be important in treatment selection and patient counseling. To date, comorbidity has not been incorporated into clinical staging of head and neck cancer patients.

STAGING OF NECK CANCER

Staging of the neck for metastatic squamous cell carcinomas of the head and neck is based on the TNM classification formulated by the American Joint Committee on Cancer (AJCC) [see 2:1 *Oral Cavity Lesions*]. The N classification applies to cervical metastases from all upper aerodigestive tract mucosal sites except the nasopharynx; nodal metastases from cutaneous, sinonasal, and thyroid malignancies have their own staging systems.

The purpose of staging is to characterize the tumor burden of an individual patient. Precise characterization and differentiation of tumors facilitate identification of those patients who are most likely to benefit from treatment. However, the TNM staging system does not include a number of factors that are known to have an impact on prognosis, such as the presence or absence of ECS and the pattern of lymphatic spread. Nonanatomic factors (e.g., comorbidity, immune status, and nutritional status) have a strong impact on survival as well but are also not incorporated in the current staging system. In general, TNM staging may be inadequate for use in clinical trials.¹⁴

The limitations of clinical staging of the neck are well described. In particular, patients with short, thick necks are challenging to stage accurately on physical examination alone. The addition of imaging to clinical examination improves diagnostic sensitivity but not specificity. Pathologic review of neck specimens remains the gold standard for anatomic staging. The addition of ultrasound-guided FNA of neck nodes yields enhanced diagnostic accuracy in cases in which the neck is clinically negative, but the radiologic findings are positive. This approach is employed to select patients for neck dissection in a number of centers, particularly in Europe; whether it provides more accurate staging than alternative methods, such as SLN biopsy, remains to be determined. The results from the First International Conference on Sentinel Node Biopsy in Mucosal Head and Neck Cancer revealed that SLN biopsy of the clinically negative neck has a sensitivity comparable to that of a staging neck dissection.¹⁵ In general, imaging modalities

appear to be neither sufficiently sensitive nor sufficiently specific in the evaluation of the clinically negative neck. Uptake of 2-deoxy-3 [^{18}F] fluoro-D-glucose, as measured by PET scans, is undetectable in small foci of cancer in the clinically negative neck.¹⁶

Proper staging is important for stratification of patients into risk categories on the basis of tumor biology so that high-risk patients may be appropriately selected for clinical trials or offered adjuvant therapy and other patients may be spared unnecessary treatment. Until accurate methods of assessing the clinically negative neck are developed, selective neck dissection will be performed to treat the neck when the occult metastatic rate is expected to be higher than 20%.

INDICATIONS FOR NECK DISSECTION

Neck dissections are considered either therapeutic (performed to remove clinically identifiable cancer in the neck) or elective (performed when the expected incidence of occult metastases from a lesion exceeds 20%). In patients with head and neck cancer, neck dissection may be performed as part of initial definitive treatment, often combined with resection of the primary cancer. Alternatively, neck dissection may be performed in an adjuvant setting to remove residual cancer in the neck following treatment with radiation or chemoradiation. Technically, neck dissections are classified as comprehensive dissections, which incorporate five levels of the neck, or selective dissections, in which only selected lymph node levels are removed according to predicted drainage patterns from specific primary sites. There is also a third technical classification, extended neck dissections, which can be combined with selective or comprehensive neck dissections for removal of additional nodal basins [see Operative Planning, Choice of Procedure, below]. Six lymph node drainage basins in the neck are recognized [see Figure 1]. The extent of neck dissection is determined by the clinical setting.

CONTRAINDICATIONS TO NECK DISSECTION

The only absolute contraindication to neck dissection is surgical unresectability. The determination of unresectability is made by the operating surgeon either preoperatively, on the basis of imaging studies, or in the operating room. Typically, the presence of Horner syndrome, paralysis of the vagus nerve or the phrenic nerve, or invasion of the brachial plexus or the prevertebral muscles indicates that the tumor is unresectable. The involvement of the carotid artery may be predicted on the basis of imaging studies. Encasement of the carotid artery by tumor suggests direct invasion of the vessel; however, studies correlating imaging characteristics and pathologic invasion of the carotid have shown that tumors surrounding 180° or more of the carotid's circumference have a higher incidence of carotid invasion than tumors surrounding less than 180° (75% versus 50%). In the absence of direct invasion of the vessel wall, tumor may be peeled off by means of subadventitial surgical dissection. Tumors surrounding 270° of the vessel have an 83% incidence of carotid invasion, necessitating sacrifice of the artery.¹⁷ However, sacrifice of the carotid artery, with or without reconstruction with a vein graft, has been associated with significant morbidity. The survival of patients with such extensive neck disease is uniformly poor.¹⁸

Figure 1 Cervical lymph nodes are divided into six levels on the basis of their location in the neck.

Operative Planning

CHOICE OF PROCEDURE

Comprehensive Dissection: Radical and Modified Radical Neck Dissection

The radical neck dissection was first described in 1906 by George Crile, who based his approach on the Halstedian principle of en bloc resection. The procedure was subsequently standardized by Hayes Martin at Memorial Hospital in New York in the 1930s and 1940s. In this latter version of the procedure, lymphatic structures from the strap muscles anteriorly, the trapezius posteriorly, the mandible superiorly, and the clavicle inferiorly are removed. Nonlymphatic structures in this space are also sacrificed, including the spinal accessory nerve, the sternocleidomastoid muscle, the internal and external jugular veins, the submandibular gland, and sensory nerve roots. The routine sacrifice of the spinal accessory nerve, the internal jugular vein, and the sternocleidomastoid muscle contributes to the significant morbidity associated with radical neck dissection.

Since the 1970s, the necessity of en bloc resection for oncologic cure has been reexamined. Structures once routinely sacrificed are now routinely preserved unless they are grossly involved with cancer. The various functional, or modified, radical neck dissections are classified according to which structures are preserved. Type I dissections preserve the spinal accessory nerve; type II, the spinal accessory nerve and the internal jugular vein; and type III, both of these structures, along with the sternocleidomastoid muscle. Modified radical neck dissections have proved to be as effective in controlling metastatic disease to the neck as the classic radical neck dissection.¹⁹

Selective Neck Dissection

In a selective neck dissection, at-risk lymph node drainage basins are selectively removed on the basis of the location of the primary tumor in a patient with no clinical evidence of cervical lymphadenopathy. Cancers in the oral cavity, for example, typically metastasize to levels I through III and, occasionally, IV; laryngeal cancers typically metastasize to levels II through IV. The rationale for selective neck dissection is based on retrospective pathologic reviews of radical neck dissection specimens from patients without palpable lymphadenopathy. These reviews revealed that lymph node micrometastases were confined to specific neck levels for a given aerodigestive tract site.²⁰

The advantages of selective neck dissection over radical and modified radical neck dissection are both cosmetic and functional. A selective neck dissection involves less manipulation (and thus less risk of devascularization) of the spinal accessory nerve, thereby decreasing the incidence of postoperative shoulder dysfunction. Preservation of the sternocleidomastoid muscle alleviates the cosmetic deformity seen with a radical neck dissection and provides some protection for the carotid artery. Preservation of the internal jugular vein decreases venous congestion of the head and neck and is necessary if the contralateral internal jugular vein is sacrificed.

In the presence of multiple pathologically positive lymph nodes or evidence of ECS, adjuvant therapy is indicated.²¹ Accordingly, selective neck dissection may be viewed as a diagnostic and a therapeutic procedure. To date, however, no randomized clinical trials have demonstrated that selective neck dissection with adjuvant treatment as needed is better than so-called watchful waiting with regard to prolonging survival in patients who present without evidence of cervical metastatic disease. Therefore, it is not yet possible to justify the added cost and morbidity of elective neck dissection in patients without evidence of metastatic disease. SLN mapping may facilitate pathologic staging in this setting and spare low-risk patients from unnecessary interventions; however, its sensitivity and specificity for this purpose are still under investigation.

The growing focus on preservation of function and limitation of morbidity has led some surgeons to promote the use of selective neck dissection to treat node-positive neck tumors. Although retrospective studies have suggested that a selective neck dissection may be adequate in carefully selected node-positive patients,²² the effectiveness of this approach is still unproven, and its application remains subject to individual surgical judgment.

Extended Neck Dissection

Extended neck dissections can be combined with selective or comprehensive neck dissections to remove additional nodal basins, such as the suboccipital and retroauricular nodes. These groups of nodes, which are located in the upper posterior neck, are the first-echelon nodal basins for posterior scalp skin cancers. The retroauricular nodes lie just posterior to the mastoid process, and the suboccipital nodes lie near the insertion of the trapezius muscle into the inferior nuchal line. Cancers of the anterior scalp, the temple, and the preauricular skin drain to periparotid lymph nodes; these lymph nodes are removed in conjunction with a parotidectomy

[see 2:6 Parotidectomy]. Retropharyngeal nodes may be removed in the treatment of selected cancers originating in the posterior pharynx, the soft palate, or the nasopharynx. A mediastinal lymph node dissection may be combined with a neck dissection in the treatment of metastatic thyroid carcinomas.

Bilateral Neck Dissection

With primary lesions located in the midline in the base of the tongue, the supraglottic larynx, or the medial wall of the piriform sinus, bilateral regional metastases are common, and bilateral neck dissections are therefore indicated. Provided that at least one internal jugular vein is preserved, bilateral neck dissection is well tolerated. In contrast, sacrifice of both internal jugular veins is associated with significant morbidity, including increased intracranial pressure, syndrome of inappropriate antidiuretic hormone secretion, airway edema, and death. Bilateral internal jugular sacrifice is managed by staging the neck dissections or by carrying out vascular repair.

NECK DISSECTION AFTER CHEMORADIATION

The indications for neck dissection have been significantly affected by the increasing use of organ preservation protocols for the treatment of head and neck cancer. Nasopharyngeal carcinomas, which are uniquely radiosensitive, are generally treated with irradiation, with or without chemotherapy. Following chemoradiation, neck dissection is reserved for patients with an incomplete clinical response to treatment who are at high risk of cancer recurrence in the neck. Most patients with early nodal disease (N0 or N1) treated according to organ preservation protocols do not require neck dissection. Patients who have advanced neck disease (N2 or N3) are less likely to respond completely to nonsurgical treatment and require a neck dissection. Early surgery (within 8 to 10 weeks) is recommended for a number of reasons. After this period, progressive soft tissue fibrosis develops, resulting in difficult surgical dissection and increased postoperative morbidity. Over time, surgery is also less effective in clearing disease from the neck, and surgical treatment of such so-called neck failures is rarely curative.²³ Observation of necks suspected of harboring residual cancer after chemoradiation is therefore not recommended. Since observation may lead to nonsalvageable regional recurrences, some surgeons recommend that all patients presenting with N2 or N3 cervical lymphadenopathy undergo planned neck dissection, regardless of clinical response to chemoradiation therapy.²⁴ Others recommend that imaging with CT of the neck be used to evaluate clinical response following chemoradiation to determine the need for neck dissection.²⁵ The presence of nodes on CT scan measuring greater than 1.5 cm or any nodes with focal lucency, enhancement, or calcification suggest the presence of residual disease. In their study, only 2 of 34 patients (6%) with a complete radiographic response were found to have residual cancer in the neck dissection specimen, suggesting that this imaging modality is a sensitive means by which to identify patients at high risk for harboring residual disease after chemoradiation.

The required extent of planned neck dissection after chemoradiation is still under investigation. Pathologic reviews of comprehensive neck specimens after chemoradiation reveal that in patients with oropharyngeal cancer, levels I and V are rarely involved in the absence of radiographic abnormalities,²⁶ which suggests that a planned selective dissection involving

levels II through IV may be sufficient for oropharyngeal cancer patients treated with chemoradiation. This more limited approach undoubtedly causes less morbidity, but additional data are required to assess its oncologic efficacy.

For patients in whom no primary site can be identified, neck dissection followed by radiation is usually recommended. This approach has also been used selectively to treat bulky nodal disease in patients with small primary cancers, although this practice is controversial.²⁷ Bulky cervical adenopathy is unlikely to exhibit a complete pathologic response to nonsurgical treatment, and postradiotherapy neck dissections are generally associated with higher rates of surgical complications. A patient who requires dental extractions before radiation therapy may undergo a neck dissection at the same time, proceeding to radiation therapy 10 to 14 days after operation. Early neck dissection decreases the tumor burden, thereby allowing lower adjunctive doses of radiation to be delivered to the neck. Significant delays in initiating treatment to the primary site should be avoided.

RECONSTRUCTION AND RECURRENCE AFTER NECK DISSECTION

The use of microvascular free tissue transfer to reconstruct surgical defects in the head has allowed surgeons to resect large tumors with large margins while simultaneously achieving improved functional results. Preservation of vascular—and, occasionally, neural—structures during neck dissection

may facilitate the reconstructive process. Typically, several vessels, including an artery and one or two veins, are required for inflow and outflow into a free flap. The facial artery, the retromandibular vein, and the external jugular vein, which are preserved during level I and level II dissection, are the vessels that are most frequently used for flap revascularization. If these vessels are unavailable as a consequence of high-volume neck disease, the superior thyroid artery and the transverse artery, with companion veins, are suitable substitutes. To date, there is no evidence in the literature that preservation of vascular structures in the neck predisposes patients to regional recurrence. Caution must, however, be exercised in the setting of pathologic lymphadenopathy.

Operative Technique

RADICAL NECK DISSECTION

Step 1: Incision and Flap Elevation

When a radical or modified radical neck dissection is indicated, appropriate neck incisions must be designed so as to facilitate exposure while preserving blood flow to the skin flaps [see Figure 2]. The incision provides access to the relevant levels of the neck, affects cosmesis, and determines the extent of lymphedema and postoperative fibrosis (“woody” neck), especially in previously irradiated areas. If a biopsy was previously performed, the tract should be excised and incorporated

Figure 2 Illustrated are incisions used for neck dissections. Incision design is a critical element of operative planning. Incisions are chosen with the aims of optimizing exposure of relevant neck levels and minimizing morbidity. The incisions depicted in (a) and (b) are useful for selective neck dissections. For the more extensive exposure required in a radical or modified radical neck dissection, a deeper half-apron-style incision (c) may be used, or a vertical limb may be dropped from a mastoid-submental incision (d); the latter incision is less reliable and may break down, exposing vital structures such as the carotid. The incision depicted in (e) is also useful for selective neck dissections. The Macfee incision (f) provides limited exposure and results in persistent lymphedema in the bipedicle skin flap.

into the new incision. When a total laryngectomy is done, the stoma may be fashioned separately from the neck incision; in the event of a pharyngocutaneous fistula, the salivary flow will be diverted away from the stoma.

Once the incision is made, subplatysmal flaps are raised. If there is extensive lymphadenopathy or extension of tumor into the soft tissues of the neck, skin flaps may be raised in a supraplatysmal plane to ensure negative surgical margins. Such flaps, however, are not as reliably vascularized as subplatysmal flaps. Clinical judgment must be exercised in these situations. The flaps are raised to the mandible superiorly, the clavicle inferiorly, the omohyoid muscle and the submental region anteriorly, and the trapezius posteriorly. Radical neck dissection for bulky cervical adenopathy typically necessitates wide exposure of levels I through V. If a vertical limb is used [see Figure 2d], it must not be centered over the carotid artery, because of the risk of potentially catastrophic dehiscence. Deep utility-type incisions yield more limited exposure of level I but provide reliable vascular inflow to skin flaps.

Step 2: Dissection of Anterior Compartment

Embedded within the fascia overlying the submandibular gland is the marginal mandibular branch of the facial nerve, which must be elevated and retracted to prevent lower-lip weakness. The submental fat pad is then grasped, retracted posteriorly and laterally, and mobilized away from the floor

of the submental triangle. The omohyoid muscle is identified inferior to the digastric tendon and followed inferiorly to the sternocleidomastoid muscle. The omohyoid muscle forms the anteroinferior limit of the dissection.

Fat and lymphatic structures are dissected away from the digastric muscle and the mylohyoid muscle. The hypoglossal and lingual nerves lie just deep to the mylohyoid muscle and are protected by it [see Figure 3]. In this region, the distal end of the facial artery can be identified and preserved as needed for reconstructive purposes. Once the posterior edge of the mylohyoid muscle is visualized, an Army-Navy retractor is inserted beneath the muscle to expose the submandibular duct, the lingual nerve with its attachment to the submandibular gland, and the hypoglossal nerve. The submandibular duct and the submandibular ganglion, with its contributions to the gland, are ligated, and the submandibular gland is retracted out of the submandibular triangle.

The posterior belly of the digastric muscle is then identified inferior to the submandibular gland and skeletonized to the sternocleidomastoid muscle posteriorly, where it inserts on the mastoid tip. The specimen must be mobilized off structures just inferior to the digastric muscle. To prevent inadvertent injury, it is essential to understand the relationships among these structures [see Figure 3]. The hypoglossal nerve emerges from beneath the mylohyoid muscle and passes into the neck under the digastric muscle. It then loops around the external carotid artery at the origin of the occipital artery and
